DEDICATION

This work is dedicated to my parents whose love, encouragement and support have given me the strength to follow my passion for science and helping others.

ACKNOWLEDGEMENTS

I would like to acknowledge the people and the support received which made this dissertation possible. First, I would like to thank God for your enduring love and care which has given me the strength and motivation throughout my Ph.D. studies and will continue to guide me in my future ventures.

Secondly, I would like to thank my family. Mom and Dad thank you for your prayers. Mom thanks for your care, support and daily calls to make sure I was on track and lifting my spirit when things did not work as anticipated. Dad thanks for helping me keep focus on the big picture and not to lose sight of my end goals. To my brothers, Omar and Marcos, thanks for your love and motivation.

I would also like to give special thanks to my mentor, Dr. Theodore Cummins. Thank you for giving me the space to explore new ideas and pushing me to be a better scientist. I am immensely grateful for all your support, attention and guidance that allowed me to be grow and be productive. Thanks to my past mentors, Dr. Jorge Colon and Dr. Alexander Obukhov for investing in me. Your teachings and advice, I carried with me and have helped me through this process. I would also like to acknowledge my fellow SPINES and mentors from the Marine Biology Lab Course 2013. Your friendship, mentorship and advice

helped me in more ways that I can explain. Thank you for believing in me and motivating me to go beyond my comfort zone and dare to dream.

I would like to thank my thesis committee advisors, Dr. Grant Nicol, Dr. Richard Day, Dr. Andy Hudmon and Dr. Jill Fehrenbacher. Thank you for challenging me to think about my research from different points of view. Thank you for training me in new techniques and providing advice on experimental procedures which truly helped me throughout my research. Your feedback and constructive criticism has enhanced the quality of this research.

I would also like to thank our collaborators who have been instrumental for our research. Many thanks to Dr. Michael Vasko, Dr. Ruizhong Wang, Dr. Jun-Ming Zhang, Dr. Wenrui Xie and Dr. Judith Strong. Your knowledge, training, and feedback were pivotal to overcoming key hurdles.

Special thanks to past and present members of the Cummins lab, Yucheng Xiao, Andrew Piekarz, Zhiyong Tan, Zifan Pei, Reesha Patel, James Jackson, Adrienne Jackson, Emily Mason, Claudia Pan and Andrew Johnson for all your support. It has been fun sharing science, our lives (the ups and the downs) and watching each other grow into new stages of our lives and career.

Thanks to the administrative staff from the Pharmacology and Toxicology department Joanna Plew, Lisa King, Amy Lawson, Dan Smith, Andy Boyll,

Alexandra Guzik and STARK Neuroscience Research Institute, Nastassia Belton, for your help and support. Thank you for helping me navigate the grant submission process, paperwork for my graduate studies and keeping me on track. Thanks to all the students, post-docs and faculty from the Department of Pharmacology and Toxicology for your valuable input in seminars and journal clubs.

Thanks to the IUSM Graduate Department. In particular, past and present directors Monica Henry and Tara Hobson-Prater. Thanks Monica for making the transition from Puerto Rico easier, knowing that I had someone that I could count on and had my best interest at heart made me feel confident during this process. Tara, I have no words to say how much you have helped. Thank you for always being available to help and for your support as I navigated future directions. Thanks for believing in a more inclusive and diverse student body, your help with SACNAS and for letting me be part of recruitment process. I truly enjoyed being part of the IUSM community.

Lastly, this research would have not been possible without the support of the National Institute of Medicine. In particular, thanks to the National Institute of Neurological Disorders and Stroke for funding my training through Diversity Supplement-NS053422 and Ruth L. Kirschstein National Research Service Award Individual Predoctoral Fellowship-F31NS090837.

Resurgent sodium current modulation by auxiliary subunits in dorsal root ganglia
neurons and potential implications in pain pathologies.

Increased electrical activity in peripheral sensory neurons contributes to pain. A unique type of sodium current, fast resurgent current, is proposed to increase nerve activity and has been associated with pain pathologies. While sodium channel isoform Nav1.6 has been identified as the main carrier of fast resurgent currents, our understanding of how resurgent currents are modulated in sensory neurons is fairly limited. Thus the goal of this dissertation was to identify resurgent current modulators. In particular, we focused on sodium channel beta subunits (Nav β s) and fibroblast growth factor homologous factors (FHF) in dorsal root ganglion (DRG) neurons. We hypothesized that Nav β 4 and FHF2B act as positive regulators by mediating resurgent currents and modulating Nav1.6 inactivation, respectively. In contrast, we hypothesized FHF2A negatively regulates resurgent current by increasing the probability of channels in inactivated states. Thus, the aims of this dissertation were to 1) determine if Nav β 4 regulates fast resurgent currents in DRG neurons, 2) examine the effects of Nav β 4 knockdown on resurgent currents, firing frequency and pain associated behavior in an inflammatory pain model and 3) determine if FHF2A and FHF2B functionally regulate Nav1.6 currents, including resurgent currents in DRG neurons. To examine the aims, we used biochemical, electrophysiological and

behavioral assays. Our results suggest that Nav β 4 is a positive regulator of resurgent currents: in particular, the C-terminus likely mediates these currents. Localized knockdown of Nav β 4 decreased inflammation-induced enhancement of resurgent currents and neuronal excitability, and prevented the development of persistent pain associated behavior in an inflammatory pain model. FHF2B increased resurgent currents and delayed inactivation. In contrast, FHF2A limited resurgent currents; an effect that is mainly contributed by FHF2A's N-terminus activity that increased accumulation of channels in inactivated states. Interestingly, in an inflammatory pain model FHF2B was upregulated and FHFA isoforms were downregulated. Together these results suggest that FHF2A/B modulation might contribute to enhanced resurgent currents and increased neuronal excitability observed in the inflammatory pain model. Overall, our work has identified three resurgent current modulators FHF2A, FHF2B and Nav β 4. Manipulation of these proteins or their activity might result in novel strategies for the study and treatment of pain.

INTRODUCTION

Overview

Pain is one of the prevalent reasons why people in the United States seek medical care. According to the National Center for Health Statistics, around 76.2 million people experience persistent pain (1). A third of these people who experience pain find that it is so significant that it impacts their daily routine (2). One of the main problems faced in pain management, especially management of persistent pain, is that the available therapeutics either are ineffective or have unwanted side effects (1). Such a high incidence of pain and inadequate relief creates a need for the development of new therapeutics.

Peripheral sensory neurons are an important component of the neuronal network that processes pain sensations. In mammals, these neurons are pseudounipolar neurons, possessing one axon that sends branches into two areas: one to the periphery (e.g., skin, muscle, internal organs) and the other to the spinal cord & brainstem of the central nervous system (CNS). The peripheral branch can detect changes in mechanical, thermal or chemical input and relay the information through the branch that projects to the CNS. Typically, when a noxious stimulus is encountered, “pain-sensing” peripheral sensory neurons or nociceptors are activated (3). Alterations in the signaling process that relays painful stimuli to the CNS (i.e. nociception) are a common mechanism in pain

pathologies. In particular, increased firing of nociceptors in dorsal root ganglia (DRG) and trigeminal ganglia (TG) often results in increased pain (4-7).

Voltage-gated ion channels contribute to the excitability of sensory neurons. In particular, voltage-gated sodium channels (VGSCs or Nav) are classically viewed to generate the rising phase of the action potential (AP). There is strong evidence from genetic and pain model studies that support the functional relevance of VGSCs in pain sensations (8-12). For example, in humans and mice loss-of-function of the VGSC isoform, Nav1.7, is associated with congenital indifference to pain. Furthermore, alterations to the activity of other VGSC isoforms such as Nav1.3, Nav1.6, Nav1.8 and Nav1.9 have also been associated with pain pathologies (13-16). This evidence suggests that inhibition of specific VGSC isoforms or selective blockade of altered activity may provide new therapeutic strategies for pain. In particular, specific patterns or modes of sodium current activity are likely to be important in the perception of noxious stimulus (i.e., nociception) and the transmission of pain sensations. A novel target for altered activity in VGSC that has emerged is resurgent sodium current.

Resurgent currents, an atypical VGSC current, are thought to increase the firing frequency of neurons by providing a depolarizing drive at repolarizing voltages (17-19). Increased resurgent currents in sensory neurons have been implicated in paroxysmal extreme pain disorder (PEPD), sea anemone toxin

ATX-II induced pain, and oxaliplatin acute cooling-aggravated painful neuropathy (19-26). Under baseline physiological conditions, resurgent currents are observed in a subpopulation of DRG neurons where the major contributing isoform is Nav1.6 (27). Nav1.6 has been implicated in inflammatory and neuropathic pain models since knockdown of Nav1.6 blocks the development of persistent pain associated behaviors and increased activity of sensory neurons (14, 15). Together these findings suggest that targeting resurgent currents may provide novel strategies for pain therapeutics. However, our understanding of how resurgent currents are modulated in peripheral sensory neurons is limited. Thus, the main goal of this dissertation was to identify potential modulators of resurgent currents. In particular, we focused on the modulation of Nav1.6-mediated currents by auxiliary subunits such as beta subunits and fibroblast growth factor homologous factors (FHF).

Brief history of voltage-gated sodium channels

Our current knowledge of VGSC was spearheaded by the work of Hodgkin and Huxley in the 1950s (28-31). Hodgkin and Huxley conducted a series of experiments using the voltage clamp technique (32, 33), which enabled them to “clamp” the membrane of the squid giant axon at a specific voltage and examine the ionic currents that contributed to the generation of the action potential. They identified three main ionic currents: sodium, potassium and a small leak current (which included Cl^-). Upon depolarization the sodium conductance was

transiently activated, whereas, the potassium conductance slowly activated. Returning to the initial resting membrane potential terminated both sodium and potassium conductances. Based on their findings, they proposed a mathematical model in which the ionic conductance was dependent on the ion's permeability and electrochemical gradient (34). Additionally, they introduced a novel concept of regulation for the sodium and potassium conductances by charged particles that acted as gates. Movement of these gates was dependent on the membrane potential (i.e., voltage-gated) and time. Therefore, based on their model, sodium currents contributed to the rising phase of the action potential, whereas sodium current inactivation coupled with potassium current activation contributed to the downward phase of the action potential.

Years later, it was discovered that toxins derived from pufferfish and shellfish selectively inhibited sodium currents (35-39). In contrast, the quaternary ammonium cation, tetraethylammonium ion (TEA), selectively inhibited potassium currents (37, 38, 40, 41). These experiments confirmed that sodium and potassium currents were generated by specific channels or receptors which Hodgkin and Huxley eluded to as "particles occupying the membrane" (34). During the 1960-70s, several functional properties of "sodium receptors" were elucidated giving birth to new conceptual models for an ion selectivity filter, pore structure of the channel, and activation and inactivation gates (42-48). However, the actual VGSC protein was not identified until the 1980s, when the subunits of VGSC were purified from brain tissue. These studies revealed a multimeric

complex composed of large alpha (α)-subunits associated with smaller beta (β)-subunits (49-51). It was during this time that a major breakthrough was achieved, the first sodium channel α subunit was cloned (52, 53). Expression of the α subunit was sufficient to produce a functional channel. Together, cloning of VGSC subunits and the advancement of high resolution patch clamp techniques, propelled the study of VGSCs (54, 55).

Voltage-gated sodium channel

VGSCs are transmembrane proteins that selectively mediate the inward flow of sodium ions generating the rapid upstroke of the AP (56). Nine α subunit genes that encode VGSC isoforms (Nav1.1 - Nav1.9) have been identified in mammals. The overall structure of the nine α subunit isoforms is highly conserved as a single polypeptide sequence (~2,000 amino acids) organized into four homologous domains (DI-DIV) each with six transmembrane segments (S1 - S6; Figure 1A). The α subunit folds into a pseudotetrameric tridimensional structure in which S5/6 segments within each domain form an aqueous pore module selectively permeable to sodium ions. The S1-4 segments form the voltage sensor domain arranged around the pore module. In particular, S4 within each domain contains positive residues sensitive to changes in membrane potential and movement of the voltage sensors produces conformational changes in the protein structure (53, 57, 58). In this manner, VGSCs change between conformations that either conduct sodium ions (open state) or are

nonconducting (inactive states and closed states). Classically, sodium currents are generated when the membrane is depolarized and channels become activated or open. Sodium currents are then terminated by channel inactivation (Figure 1B-C). There are different modes of inactivation and these are discussed below. The most common mode of inactivation is fast inactivation which is mediated by the cytoplasmic linker between DIII-DIV. In particular, the IFM (Isoleucine-Phenylalanine-Methionine represented as the inactivation particle in Figure 1) motif within this linker is essential (59). Movement of the inactivation particle occludes the pore as a hinged lid by interacting with a putative receptor in the VGSC structure (60). Once inactivated, VGSCs become refractory and require repolarization of the membrane to recover before they are available again (61).

Many of the α subunits have developmental and tissue specific distributions (62). For example, Nav1.4 is predominantly expressed in skeletal muscle (63). In contrast, Nav1.5 is predominantly in cardiac tissue (64). Nav1.3 is predominantly expressed in immature neurons and downregulated in mature neurons (65). Nav1.7, Nav1.8 and Nav1.9 are predominantly expressed in the peripheral nervous system (PNS). In contrast, in mature CNS neurons the predominant isoforms are Nav1.1, Nav1.2 and Nav1.6, however Nav1.1 and Nav1.6 are also expressed in PNS (66, 67).

Figure 1: Structure and function of VGSC. **A**, Linear Representation of VGSC α subunit. Regions highlighted in blue represent the regions between S5 and S6 that yield the aqueous pore module selectively permeable to sodium. **B**, Cross-sectional representation of VGSC conformational changes in response to changes in membrane potential. **C**, Representative trace of whole cell patch clamp recording of sodium current upon a depolarizing voltage step stimulus and corresponding state transitions from closed–open–inactive states.

Sodium channels in DRG neurons

Peripheral sensory neurons, at least in mammals, differ from neurons in the CNS neurons in a number of ways, including morphology and physiology (68). Although it has been written that with VGSCs “one is impressed more with the similarity of function than with the differences”(56) , this is clearly not the case with sodium currents in peripheral sensory neurons where sodium currents exhibit broad diversity. While sodium currents in the CNS are, for the most part, highly sensitive to pufferfish’s tetrodotoxin (TTX; IC₅₀s near 10nM), distinct

components of the complex currents that can be elicited in peripheral DRG and TG neurons are roughly 1,000 to 50,000 fold less sensitive. As such, VGSC currents in DRG neurons can be classified as TTX-sensitive (TTXS) and TTX-resistant (TTXR).

The kinetic diversity of sodium currents in peripheral sensory neurons is also greater than that in the CNS. Peripheral neurons may express fast, slow and persistent sodium currents (see Figure 2) (69, 70). The fast gating current can be generated by multiple TTXS isoforms including Nav1.1, Nav1.3, Nav1.6 and Nav1.7. In adult DRG neurons, Nav1.3 is not expressed but expression can be triggered following nerve injury (71). The kinetics and voltage-dependence of TTXS currents contribute to the initiation of the AP. Some isoforms may also generate small persistent currents that can influence the threshold for AP generation (72, 73). In contrast, the large slowly inactivating and persistent currents observed in peripheral sensory neurons (74-76) are TTXR. In adult DRG neurons, the slow component is mainly generated by Nav1.8. This isoform exhibits a more depolarized voltage-dependence of activation and inactivation relative to TTXS channels and contributes in a major fashion to the upstroke of AP in neurons where it is expressed (77, 78). In contrast, Nav1.9 channels can activate at more hyperpolarized membrane potentials where other VGSCs are quiescent generating the large persistent component observed in DRG neurons (Figure 2D). Expression of Nav1.5, a TTXR channel, is detected in embryonic DRG neurons but is downregulated to negligible levels in adult neurons (65, 79,

80). As such, it is not considered to be a major VGSC contributor of TTXR sodium current in adult DRG neurons (13).

Figure 2: Examples of the sodium current diversity in DRG neurons. Endogenous sodium current recordings were obtained from dissociated DRG neurons grown in culture. A single pulse of 50ms from -80 to 40 mV was used to examine the current voltage relationship of the sodium currents.. **A**, Representative traces of a DRG neuron with fast TTXS sodium currents. **B**, Representative traces of a DRG neuron with TTXR-slow sodium currents. **C**, Representative traces of a DRG neuron with TTXR-slow sodium currents. For panel B and C recordings were obtained in the presence of 500 nM TTX. Sodium currents were normalized to the peak sodium current of the DRG neurons. **D**, Normalized current as function of voltage shows that slow sodium currents (green circles) exhibit a more depolarized voltage-dependence relative to fast (blue squares) and persistent currents (red triangles). In contrast, persistent currents exhibit a more hyperpolarized voltage correlation relative to fast and slow currents.

The expression of VGSC α subunits varies between the different classes of peripheral sensory neurons. Three main classes of sensory fibers (C, A δ and A α/β) can be differentiated based on conduction velocity, soma diameter, and

activation threshold (Table 1). These different types of sensory fibers are activated selectively by the mode and intensity of the peripheral stimulus. Fibers, that are activated by a noxious stimulus, are termed nociceptors. Nociceptors are generally classified as high threshold neurons (81). While nociceptors are classically identified as fibers in the C-A δ class, there is substantial evidence that supports that a subset of A β fibers also likely function as nociceptors (82). In C-fiber neurons, the predominant VGSCs expressed are Nav1.7, Nav1.8 and Nav1.9 (74, 75, 83, 84). In contrast, A-fiber neurons predominantly express Nav1.1, Nav1.6 and, (to a lesser extent) Nav1.7 with the exception of a discrete subpopulation that also expresses Nav1.8 at high levels (83, 85, 86).

Fiber class	A α/β	A δ	C
Soma diameter	>35um Large	25-35um Medium	<25um Small
Myelination	Thick	Thin	None
Conduction	35-75m/s	5-30m/s	0.5-2m/s
Threshold	Low - high	Low - high	Low - high
VGSC (predominant α subunits)	Nav1.1, Nav1.6, Nav1.7 *Unique subpopulation express Nav1.8		Nav1.7 Nav1.8 Nav1.9

Table 1. Classification of peripheral sensory neurons

The focus of this dissertation is TTXS currents, in particular Nav1.6-mediated currents. Therefore, we used the differences of VGSCs sensitivity to TTX inhibition to isolate currents from a specific isoform in transfected DRG neurons. When examining endogenous sodium currents in DRG neurons, we use

the voltage-dependence and kinetic differences between TTXS/TTXR channels to digitally subtract the TTXR component.

VGSCs and pain

Because Nav1.7, Nav1.8 and Nav1.9 are preferentially expressed in peripheral neurons and highly expressed in typical nociceptor neurons, a great deal of attention has focused on these three isoforms. Studies of pain mechanisms in animal models, transgenic mice, and mutations identified in humans have confirmed that these three isoforms play important roles in nociception. For example, multiple studies indicated that Nav1.8 currents are substantially altered in animal models of nerve injury and inflammation (13, 87-91). A number of mutations in *SCN10A* (the gene that encodes Nav1.8) have been identified in humans with painful neuropathies (92, 93). Several of these mutations have been shown to increase sensory neuron excitability when expressed in preclinical models, helping to validate the importance of Nav1.8 in pain. In contrast, mutations in *SCN11* (Nav1.9 gene) have been identified in humans with abnormal pain sensations. Interestingly, putative gain-of-function mutations have been identified in patients with enhanced sensitivity to pain (94, 95) and patients with loss-of-pain sensations (96). Gain-of-function mutations in Nav1.7 have been identified in patients with severe neuropathic pain sensations such as PEPD and erythromelalgia (22, 97, 98). Conversely, loss-of-function mutations in Nav1.7 are associated with complete insensitivity to pain (99, 100).

However, it is unclear if Nav1.7 is crucial to all pain sensations, especially in adults. Loss of Nav1.7 from birth could predispose individuals to a complete inability to sense pain throughout life. Interestingly, animals with loss of Nav1.7 in sensory neurons do not exhibit a complete insensitivity to all pain conditions (101). This raises the possibility that specific pain conditions are independent of Nav1.7. For example, chemotherapeutic-induced pain does not appear to depend on classic nociceptors and the sensory selective isoforms Nav1.7, Nav1.8 or Nav1.9 (16, 26, 101). Instead, an atypical candidate has recently emerged, Nav1.6.

Nav1.6

Nav1.6 is an isoform that is not classically associated with sensitivity to pain, in part because its expression is restricted to peripheral sensory neurons (102-104). In addition to peripheral sensory neurons, Nav1.6 is also abundantly expressed in the adult mammalian brain and spinal cord (105). Expression has also been described in cardiomyocytes and non-excitabile cells such as macrophages, microglia and Schwann cells (106-109), albeit at lower levels. Studies with Nav1.6 null mice suggest that it is important for proper neurological function and development. In particular, Nav1.6 null animals suffer from motor disorders and do not survive past three weeks (102). Mutations identified in Nav1.6 are associated with pathologies in which brain, heart and motor functions are altered (102, 107, 110-114). As such, until recently it has not been studied in

as much detail in the context of pain as other isoforms. For example, Nav1.6 is important for the development of persistent mechanical hypersensitivity mediated by localized chemogenic inflammation of the DRG, a proposed radicular pain model (115, 116). In the early stages of inflammation, increased Nav1.6 expression was positively correlated with increased spontaneous activity (14). Localized injection (near the DRG) of small interfering RNAs (siRNA) targeted to Nav1.6 in parallel with the induction of inflammation prevented the development of persistent mechanical hypersensitivity(14). Furthermore, knockdown of Nav1.6, but not Nav1.7, abolished early stage inflammation mediated increases in electrical activity(14). While resurgent and persistent currents were not examined in this study, the increased propensity of Nav1.6 to generate these currents potentially contributes to the increase electrical activity.

The role of Nav1.6 in nociception was also investigated in two rat models of neuropathic pain (spinal nerve ligation and chronic constriction injury). Localized knockdown (as previously described) of Nav1.6 prior and at the time of nerve ligation or injury greatly reduced mechanical, but not cold-dependent pain associated behaviors (15). Nav1.6 knockdown reduced the spontaneous firing and reduced the increased firing frequency in DRG neurons that is commonly observed in these models (117, 118). Interestingly, Nav1.6 knockdown also decreased abnormal neuronal outgrowth from sympathetic neurons into DRG neurons (15). It is not clear how these new sympathetic innervation in DRG neurons alter nociception. Studies suggest that sympathetic sprouting is

stimulated by ectopic activity in DRGs (119). Abnormal sympathetic contacts may in turn stimulate DRG neurons, forming a cycle that maintains chronic pain sensations (120-122). This hypothesis is supported by the fact that in these models sympathetic sprouting was highly co-localized to DRG neurons that expressed Nav1.6 (15). One possibility is that Nav1.6 mediates initial changes that may later contribute to the maintenance of chronic pain sensation and thus targeting Nav1.6 activity (such as resurgent currents) in early stages may be a viable strategy to prevent the development of neuropathic pain.

Pharmacological and genetic manipulation of Nav1.6 in a preclinical model of oxaliplatin suggest that it is a key factor in mediating oxaliplatin-induced increases in electrical activity (16, 26). Oxaliplatin is an anticancer drug used mainly to treat colorectal cancer. The acute stage of the neuropathy arises shortly after infusion and is observed with high incidence (123). Sensory, and in some cases motor symptoms, are aggravated or triggered by cold temperatures ((124)). One study showed that DRG nerve fibers from heterozygous knockout Nav1.6 mice exhibited a dampened cold dependent increase in activity to oxaliplatin exposure. DRG fibers from homozygous knockout Nav1.6 mice exhibited no increase in electrical activity to oxaliplatin exposure (26). At a behavioral level, Deuis et al, showed reversal of cold-triggered pain associated behaviors in an oxaliplatin mouse model by selectively inhibiting Nav1.6 and Nav1.1 with a high concentration GIIIA toxin(16). Consistent with these findings, Nav1.6 activity is altered in a cold dependent manner upon exposure to

oxaliplatin. While other mechanisms may also contribute to the acute painful neuropathy, Nav1.6 may prove to be a key target that would enable the patient to withstand higher doses or more frequent treatments of oxaliplatin (16, 26, 125-127).

The role of Nav1.6 is not clear in other pain pathologies. For example, in a histological study of a trigeminal nerve injury, Nav1.6 accumulates at the proximal site of the nerve injury particularly at remodeled nodes of Ranvier (128). The remodeled nodes exhibited demyelination resulting in widened gaps in the myelin sheath. The nodes of Ranvier are important for saltatory transmission of AP along the axon (129). If the nodal structure is disrupted this may result in slower nerve conduction. On the other hand, it is possible that increased expression of Nav1.6 promotes the generation of spontaneous action potentials and thus activation of nociceptive pathways. The contribution of these changes to trigeminal pain require further study.

Another pain pathology in which the role of Nav1.6 has been controversial is painful diabetic neuropathy. In animal model studies of type 1 diabetic neuropathy (early stage) where increased pain associated behavior was confirmed, Nav1.6 levels in DRG neurons have been reported to be both upregulated (130) and downregulated (131). In a Type 2 diabetes animal model, Nav1.6 is upregulated in early stages of diabetic neuropathy, which persisted, in the later stages of the disease. In the type 2 diabetes model, changes in pain-

associated behavior were positively correlated with increased Nav1.6 mRNA levels in DRG neurons (132). Further studies may provide a better understanding of the role of Nav1.6 in painful diabetic neuropathy (Type 1 or Type 2).

While there is compelling evidence for Nav1.6's role in some pain pathologies, broadly targeting Nav1.6 might result in many unwanted side effects. Therefore, targeting specific patterns of activity such as resurgent current and persistent currents might provide a more viable strategy. Auxiliary proteins that interact with Nav1.6 are potential modulators of channel activity and may result in more selective therapeutic strategies (133, 134).

Auxiliary proteins

Beta-subunits

Auxiliary subunits can associate in multiple ways with VGSCs resulting in a variety of heteromultimers that can impact VGSC properties. Beta (β)-subunits are the most commonly known auxiliary subunit (135, 136). To date four β -subunits (Nav β 1– β 4) have been identified. These subunits share some common features which include a single transmembrane domain, an intracellular C-terminal domain, and an extracellular N-terminal domain (135). β -subunits can associate with α subunits non-covalently (Nav β 1, β 3) or covalently (Nav β 2, β 4) (137). All β -subunits are expressed in DRG neurons although distribution can

vary between specific DRG sub-classes (133, 138). For example, Nav β 4 (a subunit that has been associated with the generation of resurgent currents) is expressed at higher levels in the medium to large compared to the population of small diameter neurons (23, 138). In a similar manner Nav β 1 is more abundant in medium to large population than in small diameter neurons and Nav β 3 is more abundant in small diameter neurons than in the medium to large population of DRG neurons. Nav β 2 is ubiquitously expressed throughout the different size classes (139).

β -subunits can alter the expression and biophysical properties of the channel such as gating, current density, persistent current and resurgent current (140). These effects can vary depending on the α -subunit expression, and cell background. For example, in small diameter neurons, deletion of Nav β 2 decreased the expression of TTXS channels and increased the rate of activation and inactivation. However, TTXR channels were not significantly modulated (141). In contrast, Nav β 1 deletion decreased the expression of Nav1.9 and shifted the voltage-dependence of inactivation for TTXS channels to positive potentials, which resulted in hyperexcitability of small diameter neurons (142). There is good evidence to support the potential role of β -subunits in pain sensations. For example, Nav β 2 null mice exhibit reduced pain behavior responses after nerve injury (141). In contrast, upregulation of Nav β 3 in sensory neurons has been associated with increased pain responses in different animal models (139, 143, 144). The role of Nav β 4 in pain sensations has not been fully

explored and is one of the aims of this dissertation. Additionally, β -subunits can act as cell adhesion molecules (CAM) (145). As such, β -subunits may also be important for neuronal outgrowth(136, 146, 147). However, this potential role and implication to pain sensations has not been extensively studied in sensory neurons and will not be explored in this dissertation.

Fibroblast growth factor homologous factors

FHFs are intracellular signaling proteins expressed mainly in excitable cells. Contrary to their homologue counterparts (i.e. fibroblast growth factors), FHFs are neither secreted nor activate FGF-Receptors (148). While FHFs can interact with multiple partners including microtubules (149), kinases (150), scaffolding proteins (151, 152), nuclear factors (153) and calcium channels (154); their interaction with VGSCs (134, 148) qualifies them to be considered as VGSC auxiliary proteins. To date four FHF genes have been identified in vertebrate species (FHF1-4). Each FHF gene can result in multiple isoforms through alternative splicing and promoter usage resulting in distinct N-terminal sequences (155). Two commonly identified isoforms are FHF Type A (FHFA) and FHF Type B (FHFB). FHFBs are cytosolic. In contrast, FHFA contain a bipartite nuclear localization signal that depending on the properties of the cell background may be active or silent (156). Both “A” and “B” isoforms of FHF have conserved core domains that enable them to bind to the C-terminus of sodium channels (157-160). FHF interaction with VGSC can alter the biophysical properties of

activation, inactivation and current density (148, 161). In particular, FHF's binding to the C-terminus of VGSC shifts the voltage-dependence of inactivation. For example, heterologous co-expression of FHF2 and FHF4 isoforms with Nav1.6 consistently shifted the voltage-dependence of inactivation to positive potentials, whereas, differential effects were observed in current density depending on isoform and cell background.

Adult DRG neurons can express a variety of FHF isoforms including FHF1, FHF2 and FHF4 (134, 162-165). FHF1 is present mainly as variant B (FHF1B), since FHF1A is downregulated in adult animals. FHF1 expression is found in membrane, cytosol and nucleus; therefore, the FHF1A nuclear signal is predicted to be active in DRG neurons. A potential interaction of FHF1B with Nav1.9 was identified. However, this interaction is not predicted to occur in sensory neurons since both proteins are not generally expressed together in the same population of DRG neurons (159, 164). FHF2 variants colocalize with Nav1.6 in different subpopulations of DRG neurons: FHF2A colocalizes with Nav1.6 in C-fibers, whereas, FHF2B colocalizes with Nav1.6 in A-fibers (162, 163). The FHF2A nuclear localization signal is predicted to be silent since expression is detected at the membrane and in the cytosol of DRG neurons, but not the nucleus. FHF3 expression has not been studied in sensory neurons in much detail (148). Overall, there has not been extensive research of FHF's contribution to pain pathologies. Two studies using cDNA arrays reported FHF2 cDNA levels were downregulated with no change in FHF1 and FHF4 after

peripheral nerve injury (165, 166). Which of the FHF2 isoforms contribute to this change and how these changes translate to changes in VGSC is not known. One possibility is modulation of resurgent currents since FHF2s are proposed to modulate resurgent current generation in CNS neurons (167). Because of the gap in knowledge, modulation of resurgent current by FHF2 isoforms is one of the areas explored in this dissertation.

Overall, VGSCs subunits can form heteromultimeric complexes with a diverse combination of α subunits and auxiliary proteins. Although the focus of this dissertation is modulation of Nav1.6 currents by β -subunits and FHF2 isoforms, these proteins are not the only partners known to interact with VGSCs. Numerous other proteins have been identified that reportedly interact with α subunits including calmodulin, ankyrins, multiple protein kinases, Nedd4-2, CRMP2, syntrophin, contactin, annexin II light chain and KIF5 (to name a few) (168). The formation of the complexes depends on expression, colocalization and interaction between the sodium subunits and auxiliary proteins in a given cell type. As VGSC activity is modulated by interactions with auxiliary proteins, these interacting partners have the potential to be molecular regulators of excitability and nociception. In particular, we focus on how Nav β 4 and FHF2 isoforms may regulate resurgent currents, VGSC inactivation and excitability of DRG neurons.

Intrinsic mechanisms of VGSC inactivation and contributions to nociception

There are several mechanisms by which VGSCs intrinsically inactivate, and major mechanisms include fast inactivation and slow inactivation (169, 170). Fast inactivation occurs within milliseconds of channel activation, as the intracellular loop between the DIII-DIV folds (inactivation particle) and occludes the cytoplasmic face of the pore (59). Recovery from fast inactivation (i.e. channel repriming) typically occurs within 10ms. Interestingly, the DIII-DIV intracellular loop is highly conserved among the nine different isoforms, including Nav1.9 despite its dramatically slower inactivation kinetics(171). VGSCs can undergo both closed-state and open-state fast inactivation, but it is not entirely clear if the mechanisms for these two are identical. Alterations in fast inactivation are believed to be important modulators of nociceptor activity and pain sensations (7). For example, recovery from inactivation is a limiting factor for sodium channel availability to respond to an additional stimulus. Indeed, local anesthetics that target sodium channel activity in peripheral fibers are believed to act largely by stabilizing fast inactivation of VGSCs in nociceptors (172).

In contrast to fast inactivation, slow inactivation is a gradual process that occurs on the time scale of seconds to minutes through conformational changes of the channel pore (169, 170). It is less clear to what extent slow inactivation contributes to alterations in nociception. Slow inactivation of Nav1.8 seems to

modulate the duration of the AP firing in nociceptive neurons in response to sustained stimulation (173). Interestingly, slow inactivation of TTX-S channels is enhanced by cold. Enhancement of slow inactivation would result in a reduction of available TTXS VGSC to respond to a given stimulus. Thus, enhancement of slow TTXS could contribute to the ability of tissue cooling to reduce some types of pain sensations. Conversely, a lack of cold sensitivity for Nav1.8 slow inactivation is believed to be crucial to cold-induced pain sensations (174). Since, Nav1.8 slow inactivation is insensitive, this isoform would remain available to generate the rising phase of the AP in a nociceptive neuron and conduct the impulse to the CNS.

Extrinsic mechanisms: Long-term inactivation and excitability

An alternate extrinsic mechanism of inactivation is long-term inactivation, which is mediated by FHFA variants through a sequence of amino acid residues in the N-terminus domain. Long-term inactivation is a distinct and competing mechanism to fast inactivation. For FHF2A, the long-term inactivation particle is proposed to be the 20 amino acid sequence: AAAIASSLIRQKRQARERE (175). This sequence is highly conserved between all FHFA isoforms. Binding of the long-term inactivation particle to the α subunit pore prolongs the recovery period of the VGSC from 10ms to 100-400ms (175). For example in a DRG-derived cell line (ND7/23), FHF2A expression causes accumulation of channel inactivation due to slowing of recovery from inactivation (163). Current clamp simulations

incorporating long-term inactivation parameters suggest that this mechanism decreases firing frequency (175). Simulation predictions were later confirmed with hippocampal neurons, which showed that FHFAs elevated AP voltage threshold and slowed AP frequency with each consecutive stimulus (176). Long-term inactivation induced by FHFAs is a recent finding and there are no reported studies examining whether it occurs in DRG neurons. However, based on CNS and heterologous cell expression systems studies we predict that increased long-term inactivation would greatly reduce neuronal excitability and firing frequency by favoring channels to remain inactive for longer periods of times. One of the aims of this dissertation is to examine if long-term inactivation regulates resurgent currents in DRG neurons and potentially modulate neuronal excitability.

Extrinsic mechanisms: Open-channel block and nociception

In addition to long-term inactivation, open channel-block is also an extrinsic competing mechanism with classic fast inactivation (177). Although binding of the open channel blocker initially terminates sodium current, rapid unbinding of the blocker at intermediate voltages (e.g., -40 mV) allows sodium current to be uncharacteristically generated during periods where the channel is usually refractory. This mechanism is known to produce atypical currents referred to as resurgent sodium currents. The present model for resurgent current generation proposes that the open channel blocker binds at positive voltages and unbinds upon membrane repolarization (Figure 2A-B) (178-180). Open channel

block bypasses fast inactivation, enabling the channel to recover faster and have a shorter refractory period (180). Therefore, resurgent currents are predicted to increase neuronal firing frequency through a more rapid channel recovery in conjunction with the depolarizing contribution during the repolarization phase of the action potential (17-19, 181, 182). The identity of the open channel blocker in sensory neurons is not completely clear. Thus, one of the aims of this dissertation is to determine the identity of the open channel blocker in sensory neurons. In particular, we examine the potential role of Nav β 4.

Figure 3: Resurgent currents: **A**, Simplified Model of Resurgent Current State Transitions. As VGSC open upon depolarization (+30mV), the open channel blocker (represented as red sphere) competes with the intrinsic mechanism of inactivation (intracellular linker between DIII and DIV, represented by the yellow sphere). Binding of the open channel blocker terminates classic sodium current but prevents inactivation particle interaction; forcing the channel to remain in an open-blocked state. Membrane repolarization (-40mV) causes the blocker to unbind from the channel in the open-blocked state and resurgence of sodium conductance occurs (i.e.resurgent currents). Unbinding of the blocker allows channels to return to closed state directly or as they recover from classic inactivation. **B**, Representative traces of a DRG neuron with resurgent sodium current (red) and no resurgent sodium current (yellow) due to channel fast inactivation with respective voltage command protocol.

Two types of resurgent currents have been identified in DRG neurons and are classified based on their kinetics (fast and slow; Figure 4). Nav1.6 is the main contributing isoform to fast resurgent currents (27). Under normal conditions fast

resurgent currents are observed in a ~50% of medium to large diameter neurons but not in small diameter neurons (19, 27). In contrast, slow resurgent currents are mediated by Nav1.8 and are mainly observed in a small-medium diameter neurons (25). The voltage-dependence of resurgent currents is different between these two currents; fast resurgent currents peak at -45mV, whereas slow resurgent currents peak at -25 mV (Figure 3B), likely reflecting differences in binding of the open channel blocker to the pores of Nav1.6 and Nav1.8.

Figure 4: Slow and fast resurgent currents have different kinetic and voltage properties. **A**, Representative trace of slow resurgent current and **(B)** fast resurgent current obtained from DRG neurons. Peak current amplitude for slow resurgent current is -25mV (red trace) and -45mV for fast resurgent current (blue trace). **C**, Current-Voltage (I/V) curve for slow (red) and fast resurgent current (fast).

Studies of human VGSCs mutations are the first reported example of the potential contribution of resurgent currents to pain pathologies. Inherited and de-novo Nav1.7 mutations identified in patients that suffer from PEPD result in functional channels with altered inactivation properties and increased resurgent

currents (19, 21, 183-185). Recombinant expression of Nav1.7-PEPD mutant channels in sensory neurons results in hyperexcitability (22). Nav1.7 is an isoform that does not frequently generate robust resurgent currents in DRG neurons. However, PEPD mutations seem to increase the probability of binding of the open channel blocker due to delayed fast inactivation (i.e. voltage-dependence of inactivation shifted to positive potentials and in some cases accompanied by slowed rate of inactivation). DRG simulation studies of the Nav1.7-I1462T PEPD mutant showed that altered gating properties result in a decrease in the magnitude of the stimulus needed to elicit an action potential (rheobase). Interestingly, when increased resurgent currents were added into the model there was a substantial increase in the number of evoked action potentials. Therefore, resurgent currents were identified as a key factor that contributes to the increased firing frequency (19). The combined changes in rheobase and firing frequency are thought to contribute to painful sensations in PEPD patients.

Through a similar mechanism as seen with PEPD, increased resurgent currents may contribute to increased electrical activity of sensory neurons in non-inherited (acquired) pain pathologies. The first example is ATX-II induced pain. ATX-II is a VGSC site-3 neurotoxin isolated from the venom of sea anemone (*Anemonia sulcata*; (186)). Intradermal injection of ATX-II toxin into humans induces pain and itch that resembles those experienced by divers stung by the anemone, suggesting this component of the venom contributes to the pain

sensations perceived by the divers (23). Using the differential nerve block approach, A-type sensory fibers were identified to mediate the pain and itch sensations. In congruence with this observation, ATX-II increased TTXS resurgent and persistent currents in medium to large diameter neurons (associated with A-type fibers; see Table 1) but not small diameter neurons (23). Increased resurgent and persistent currents potentially increase the electrical activity in A-fibers. ATX-II's mechanism of action is likely due to direct interaction of the toxin with VGSCs. As a site-3 toxin ATX-II binds to the extracellular face of VGSCs and restricts DIVS4 voltage sensor movement (187). DIVS4 voltage sensor movement is important for the channel to change conformations that favor binding of the inactivation particle (188-190). Thus ATX-II indirectly impairs the fast inactivation process and potentially increases the binding probability of the open channel blocker (177). Other site-3 toxins from scorpions, sea anemones, and spiders may also induce painful sensations through a similar mechanism (191).

The second example is cooling aggravated oxaliplatin-induced acute painful neuropathy. As previously discussed, studies suggest Nav1.6 is a key factor in mediating oxaliplatin induced increases in electrical activity (16, 26). Consistent with these findings, fast resurgent currents and persistent currents increased in neurons from oxaliplatin treated animals as temperature decreased suggesting that this mechanism contributes to the cold aggravated painful episodes experienced by the patients. The increase in resurgent current and

persistent current is theoretically due to impaired fast inactivation, as evidenced by slower inactivation kinetics observed in medium to large diameter neurons exposed to oxaliplatin (26).

The third example is increased resurgent currents under inflammatory conditions. Several studies have shown that inflammatory mediators alter the firing properties of sensory neurons, which can result in hyperexcitability and contribute to persistent pain (192, 193). Inflammatory mediators can also increase the amplitude of fast and slow resurgent currents in sensory neurons (25). Both fast and slow resurgent currents likely contribute to hyperexcitability in inflammatory conditions. In particular, activation of Protein Kinase C (PKC) pathways (194, 195) is seen under inflammatory conditions and enhances Nav1.7 mediated resurgent currents in human embryonic kidney (HEK) (24). The phosphorylation site identified in this study is near the inactivation particle. Interestingly, this site is conserved in other isoforms (Nav1.1-Nav1.9), which may also be modulated by PKC. However, because modulation of VGSC activity can be cell background dependent and isoform dependent, further studies should explore if activation of this pathway results in the same effects as those seen with Nav1.7 in HEK cells.

Hypothesis and specific aims

While there is compelling evidence of the important role fast resurgent currents may play in nociception, our limited knowledge of how they are modulated in peripheral sensory neurons hinders our capability to target these currents. The goal of this dissertation is to address the gap in our knowledge and identify resurgent current modulators that may yield novel therapeutic targets. In particular, we focus on Nav1.6 mediated currents because they are the main carrier of fast resurgent currents. In addition, Nav1.6 activity is implicated in several pain pathologies, as previously discussed.

The first question we addressed was: what is the identity of the open channel blocker that mediates resurgent currents? Evidence from CNS studies suggest that it is part of the Nav β 4 subunit (180, 196, 197). The Nav β 4 subunit was initially identified because the cytoplasmic C-terminus contains positively charged and hydrophobic residues that have the necessary properties to act as the voltage dependent open channel blocker (180, 198). Based on this observation, a synthetic β 4 peptide was designed from the C-terminus of Nav β 4 (β 4 peptide: KKLITFILKKTREKKKECLV; (180, 199)). The synthetic β 4-peptide can reconstitute resurgent currents in cerebellar granule neurons and other cell lines that do not exhibit endogenous resurgent current. However, the role of Nav β 4 is not fully understood since heterologous expression of full length Nav β 4 is not sufficient to recapitulate resurgent current generation (183, 197, 200-202).

Interestingly, in DRG neurons, the incorporation of the $\beta 4$ peptide into the intracellular recording solution evokes resurgent currents in neurons that do not endogenously generate them (23). In DRG neurons that endogenously generate resurgent currents, the synthetic peptide increased resurgent current amplitude (25). Therefore, we hypothesized that Nav $\beta 4$ is likely the open channel blocker in sensory neurons. Thus, the first aim of this dissertation was to determine if Nav $\beta 4$ regulates fast resurgent currents in DRG neurons.

The results from the first aim suggested that Nav $\beta 4$ is a positive regulator of Nav1.6 resurgent currents and neuronal excitability (203). Therefore, we next explored the role of Nav $\beta 4$ in pain associated behavior. In some preclinical pain models including a model of radicular pain produced by localized inflammation of the DRG (LID), abnormal spontaneous activity of sensory neurons is observed as an early event, and plays a key role in initiation and maintenance of hypersensitivity (119, 121, 204-209). In the radicular pain model spontaneous activity consists of high frequency bursting that occurs predominantly in myelinated neurons. Interestingly, in vivo knockdown of Nav1.6 strongly reduced mechanical hypersensitivity as well as spontaneous activity and repetitive firing of myelinated neurons (14). The propensity of Nav1.6 to generate persistent and resurgent currents is likely key to spontaneous and repetitive firing observed in this model. In particular, resurgent currents generated are proposed to increase the firing frequency of neurons (17-19, 182, 210). Therefore, we hypothesized that Nav $\beta 4$ would be a key mediator for resurgent currents, repetitive firing and

mechanical hypersensitivity induced by inflammation in sensory neurons. As such, the second aim of this dissertation was to examine the effects of Nav β 4 knockdown on resurgent currents, firing frequency, and pain associated behavior in the LID radicular pain model.

We next addressed the question: is there a negative determinant that is preventing resurgent currents from being generated in some DRG neurons? As previously discussed, resurgent currents are normally observed in a subpopulation of medium and large diameter DRG neurons that express Nav1.6 (27). The factors that permit Nav1.6 to produce resurgent current in some cells, but not in others, have not yet been identified. We hypothesized a potential mechanism for the regulation of fast resurgent currents by integrating long-term inactivation and the resurgent current model. FHFA mediated long-term inactivation is proposed to compete with VGSC's fast inactivation and in a similar manner, open channel block also competes with fast inactivation (177). Based on these observations, we propose long-term inactivation and open channel block likely compete with each other as suggested by Goldfarb (Figure 5) (211). In a HEK cell line stably expressing Nav1.5, addition of long-term inactivation peptide reduced β 4-peptide mediated resurgent currents supporting the possibility that these particles compete with each other (176). FHF2A is capable of mediating long-term inactivation and has been shown to interact with Nav1.6. FHF2A predominantly co-localizes with Nav1.6 in small diameter neurons, a subpopulation of DRG neurons that does not usually generate resurgent currents

(163). Therefore, we hypothesized FHF2A limits fast resurgent current generation in sensory neurons.

Figure 5: Schematic representation of fast inactivation, long-term inactivation, and open channel block as competing mechanisms for the open channel state. Intrinsic fast inactivation is represented by the yellow sphere. Long-term inactivation particle is represented as a blue sphere part of the N-terminus of the FHFA protein represented as a blue octagon. Open channel blocker is represented as a red sphere.

In contrast, FHF2B does not mediate long-term inactivation, but may alter voltage-dependence and the kinetics of inactivation that may favor open channel block (148). For example, FHF4B in Purkinje neurons increased resurgent currents by slowing the rate of inactivation and shifting the voltage-dependence of inactivation to positive potentials. Thus increasing the probability of the endogenous open channel blocker to bind (167). In a similar manner, co-expression of FHF2B in several cell lines shifted the voltage-dependence of Nav1.6 to positive potentials (160, 162). Because FHF2B lacks the ability to

mediate long-term inactivation, but may retain the capability to “delay” fast inactivation, we hypothesized that FHF2B enhances the generation of resurgent currents in DRG neurons. Therefore, the third aim of this dissertation was to determine if FHF2A and FHF2B functionally regulate Nav1.6 currents, including resurgent currents in sensory neurons.

Overall, this dissertation focuses on Nav1.6 mediated resurgent sodium currents and the molecular determinants that potentially regulate them. The results of this research suggest that Nav β 4 and FHF2B are positive regulators, whereas, FHF2A is a negative determinant of fast resurgent currents generation. The results of our work could help identify potential approaches for the study and treatment of hyperexcitability associated with increased resurgent currents such as PEPD and oxaliplatin acute-painful neuropathy among many others.

PART I: Nav β 4 REGULATES FAST RESURGENT SODIUM CURRENTS AND EXCITABILITY IN SENSORY NEURONS

Summary

Resurgent currents are proposed to enable high frequency firing and increased resurgent currents in sensory neurons are associated with pain pathologies. While Nav1.6 has been identified as the main carrier of fast resurgent currents, our understanding of the mechanisms that contribute to resurgent current generation is limited. Specifically, the open channel blocker in sensory neurons has not been identified. Previous studies suggest that Nav β 4 mediates resurgent currents in CNS neurons. The goal of this study was to determine whether Nav β 4 regulates resurgent currents in DRG neurons. Our immunocytochemistry studies show that Nav β 4 expression is highly correlated with Nav1.6 expression predominantly in medium to large diameter rat DRG neurons. Nav β 4 knockdown decreased endogenous fast resurgent currents in medium to large diameter neurons as measured with whole cell voltage clamp. Using a reduced expression system in DRG neurons, we isolated recombinant human Nav1.6 sodium currents in rat DRG neurons and found that overexpression of Nav β 4 enhanced Nav1.6 resurgent currents. By contrast neither overexpression of Nav β 2 nor overexpression of a Nav β 4-mutant, predicted to be an inactive form of Nav β 4, enhanced Nav1.6 resurgent current generation. DRG neurons transfected with wild-type Nav β 4 exhibited increased

excitability with increases in both spontaneous activity and evoked activity. Thus, Nav β 4 overexpression enhanced resurgent currents and excitability, whereas knockdown or expression of mutant Nav β 4 decreased resurgent current generation. This study identified Nav β 4 as an important regulator of resurgent currents and excitability in sensory neurons. As such, Nav β 4 may be a potential target for the manipulation of neuronal excitability and pain sensations.

Materials and Methods

cDNA constructs

These studies used cDNA constructs of sodium channel β subunits, Nav β 2 and Nav β 4, which were tagged at the C-terminus to verify expression. To generate the rat Nav β 4 C-terminal tagged construct, an Apal restriction enzyme site was introduced into pCMV6 vector before the stop codon (Origene clone, RR210027) using Quickchange XL II Site Directed Mutagenesis kit (Agilent Technologies). The open reading frame for Nav β 4 protein (NP_001008880.1) between Apal and EcoRI was cut and inserted into mVenus N1 or pmTurquoise2 N1. Vectors, mVenus N1 and pmTurquoise2 N1, were gifts from Dr. Richard Day at Indiana University School of Medicine (Indianapolis, IN). Two constructs were generated using this approach: Nav β 4-Turquoise and Nav β 4-Venus. A predicted inactive form of Nav β 4-tagged (Nav β 4-Mt) was generated by converting lysines at position 192-193 and 197-199 to alanine using Quickchange XL II Site

Directed Mutagenesis kit. To generate the rat Nav β 2-tagged construct, cDNA encoding for rat Nav β 2 protein (NP_037009.1) was codon-optimized and synthesized. The *SCN2B* open reading frame was cut with NheI–AgeI and inserted into mVenus N1 vector.

To generate the Nav1.6r construct, *SCN8A* gene encoding for human Nav1.6 protein (NP_055006.1) was codon-optimized and synthesized. The open reading frame was cut with KpnI–XbaI and inserted into pcDNA3.1 vector. The resulting construct was modified by converting tyrosine 371 to serine to confer high resistance to TTX as previously described (212, 213). To isolate Nav1.6r currents, Nav1.8 was knocked down with a Nav1.8 shRNA-IRES-dsRED construct. The Nav1.8 shRNA-IRES-dsRED construct is a vector plasmid (pIRES2-dsRed) that encodes for the Nav1.8 shRNA sequence (targeting sequence, GATGAGGTCGCTGCTAAGG (214)) and an internal ribosome entry site for the translation of fluorescent protein marker dsRed (IRES-dsRED) as previously described in (19).

Cell culture

Adult rat DRG ganglia were harvested, dissociated and cultured as previously described in (19, 70, 212). Briefly, adult male Sprague Dawley rats were rendered unconscious by CO₂ exposure and decapitated. The spinal column was removed and dorsal root ganglia were harvested from the lumbar

region up to the cervical region. Excised ganglia were digested in Dulbecco' modified Eagle's Medium (DMEM, Fisher Scientific) containing collagenase (1.25mg/mL) and neutral protease (0.78mg/mL) for 45 minutes at 37°C. Ganglia were mechanically dissociated with sequentially smaller pasteur pipettes in 10% Fetal Bovine Serum (FBS, Hyclone) DMEM (Invitrogen). Glass coverslips coated with poly-D-lysine and laminin were loaded with dissociated cell suspension. After 10 minutes, cells settled and 10% FBS DMEM was added. For knockdown experiments, L4 and L5 ipsilateral dorsal root ganglia were excised from rats injected with non-targeting control or $\beta 4$ siRNA (see below). The above dissociation protocol and culture was followed with the exception of the digestion time, which was decreased, to 28 minutes. Cells were maintained at 37°C in a humidified 95% air and 5% CO₂ incubator. Media was changed every two days. For experiments longer than two days, such as isolated recordings of Nav1.6r from DRG neurons, 10% FBS DMEM was supplemented with mitotic inhibitors: 5-fluoro-2-deoxyuridine (50 μ M, Sigma Aldrich) and uridine (150 μ M, Sigma Aldrich). Indiana University School of Medicine Institutional Animal Care and Use Committee approved the animal protocols described.

Procedure for in vivo injection of siRNA near the DRG

siRNA "smartpool" consisting of four different siRNA constructs combined into 1 reagent directed against rat Nav $\beta 4$ subunit (Gene ID: 315611) and non-targeting control siRNA were purchased from Dharmacon. Catalog numbers

were M-101002-01 (directed against Nav β 4) and D-001210-02 (n.t. control, directed against firefly luciferase). The non-targeting control siRNAs are reported to: 1) not target any known rat genes, 2) have a minimum of four mismatches to all human, mouse and nontargeted rat genes, and 3) have minimal targeting confirmed by genome wide microarray analysis as stated by manufacturer. The four siRNA sequences directed against Nav β 4 were: construct 1, GGAUCGUGAAGAAUGAUAA; construct 2, UCCAAGUGGUUGAUAAAUU; construct 3, GCAAUACUCAGGCGAGAUG; construct 4, AAACAACUCUGCUACGAUC. siRNAs were prepared for transfection using cationic linear polyethylenimine-based reagents (in vivo JetPEI, Polyplus Transfection, distributed by VWR Scientific). Aliquots of 3 μ L containing siRNA/Jet Pei mixture (80pmol of siRNA) were injected into each L4 and L5 DRG on one side, through a small glass needle inserted close to the DRG as previously described by (14). Three days post-injection L4 and L5 dorsal root ganglia were harvested. 16-30 hours after culture a fraction of the DRG neurons were examined by immunocytochemistry to verify knockdown and another fraction was used for whole cell patch clamp (see next sections for more details). Indiana University School of Medicine Institutional Animal Care and Use Committee approved the experimental procedure described.

Immunocytochemistry

The expression patterns of Nav1.6 and Nav β 4 were studied in dissociated cultures of DRG neurons. DRG neurons were fixed after 24 hours in culture with 4% paraformaldehyde (0.1M phosphate buffer, pH 7.4) for 20 minutes and washed in phosphate buffered saline (PBS) three times. Cells were permeabilized in 1% Triton X-100 in PBS for 20 minutes at room temperature (~22°C), washed in PBS three times, blocked for 2 hours (10% normal goat serum, 0.1% Triton X-100 in PBS) at room temperature and washed an additional three times in PBS. Cells were then incubated in primary antibodies diluted in blocking solution overnight at 4°C. Primary antibodies used were anti-Nav1.6 clone K87A/10 (1:200, AB_2184197, UC Davis/NIH NeuroMab Facility) and polyclonal anti-Nav β 4 antibody (1:500, #Ab80539, Abcam). After three washes, cells were incubated with secondary antibodies in blocking solution for 2 hours at room temperature. Secondary antibodies used were Alexa Fluor® 488 Goat Anti-Rabbit IgG and Alexa Fluor® 594 Goat Anti-Mouse IgG (Molecular Probes, Life Technologies) at 1:2000 concentration. Coverslips were mounted in Prolong Gold Antifade (Molecular Probes) and DRG neurons imaged using Axio Observer Z1 Widefield Microscope with a 20X objective (ZEISS Microscopy). Images were analyzed using Axio Vision software (Version 4.8.2, ZEISS Microscopy). Each cell was delineated as a region of interest and correlation was determined using the colocalization module of the software. The analysis yielded the Pearson correlation coefficient between Nav1.6 and Nav β 4 fluorescence

signal and area for each cell. The data were grouped into small diameter neurons ($<400\mu\text{m}^2$) and medium to large diameter neurons ($>400\mu\text{m}^2$). The Pearson correlation coefficient was compared between small and medium to large neurons using Student's t-test. It is important to note that due to the limitations of this approach, the Pearson correlation values do not specifically represent colocalization of the proteins but rather describe the population of cells that co-express Nav β 4 and Nav1.6. Additionally, images were analyzed using NIS Elements Advance Research (Nikon®) software and mean intensity for Nav β 4 and Nav1.6 staining signal was determined for each cell by defining the region of interest. The data were grouped into small diameter neurons ($<400\mu\text{m}^2$) and medium to large diameter neurons ($>400\mu\text{m}^2$). The mean intensity Nav β 4 and Nav1.6 staining signal was compared between small and medium to large neurons using Student's t-test.

To verify knockdown of Nav β 4 protein, L4 and L5 ipsilateral DRG harvested and cultured from rats injected with non-targeting control and β 4-siRNA three days after injection were examined. DRG neurons were fixed, permeabilized, blocked and treated with primary anti-Nav β 4 antibody (1:500 dilution) and secondary antibody goat Alexa Fluor® 488 Goat Anti-Rabbit IgG (1:1000 dilution; Molecular Probe, Life Technologies). Coverslips were then mounted and imaged with a Nikon Eclipse TE2000-E confocal microscope with a 20X objective. Corrected Total Cell Fluorescence (CTCF) was calculated in Excel

(Microsoft) by applying measurements obtained from NIS Elements Advance Research (Nikon®) software using the following equations adapted from (215):

Equation 1

$$CTCF = \frac{\text{Integrated}}{\text{Density}} - (\text{Area of selected cell} \times \text{Mean fluorescence of background readings})$$

Equation 2

$$\text{Integrated Density} = (\text{Mean Intensity Value} \times \text{Area of the cell})$$

Quantification experiments were carried out independently at least three times; more than 250 cells were counted for each condition.

Nav1.6r currents in DRG neurons

The goal of these experiments was to study the modulation of Nav1.6 by β subunits: Nav β 4 and Nav β 2. DRG neurons express a variety of sodium channels, therefore, Nav1.6 current properties needed to be isolated. In order to achieve this we expressed a Nav1.6 construct resistant to TTX (i.e. Nav1.6r) as described in the cDNA constructs section. Endogenous TTXS currents were pharmacologically inhibited with the addition of 500nM TTX to the extracellular recording solution. DRG neurons can also endogenously express TTXR sodium currents: Nav1.8 and Nav1.9 (70, 75, 171). Nav1.8 currents are greatly decreased in culture (19, 216); additionally Nav1.8 was further decreased by co-

transfecting a Nav1.8 shRNA-IRES-dsRED construct to minimize contamination of Nav1.8 currents in the recordings. Nav1.9 currents are not observed under the culture and recordings conditions used (217, 218). β subunits studied, Nav β 4-WT, Nav β 4-Mt and Nav β 2, were tagged at the C-terminus with fluorescent protein (mVenus or pmTurquoise2) to verify expression as described in the cDNA constructs section. No difference was observed between modulation of the biophysical properties of human Nav1.6r by co-expression of Nav β 4-Turquoise compared to Nav β 4-Venus, thus, these constructs were used interchangeably in experiments. As a negative control, fluorescent proteins (mVenus or pmTurquoise 2) were co-transfected instead of the tagged beta subunits. No difference was observed between modulation of the biophysical properties of human Nav1.6r by co-expression of pmTurquoise2 compared to mVenus, thus these constructs were used interchangeably in experiments. The Helios Gene Gun (Bio-Rad Laboratories) was used to transiently transfect DRG neurons as previously described in (212, 218-220). DRG neurons were co-transfected 36-48 hours after dissociation with: Nav1.6r, Nav1.8shRNA-IRES-dsRED, and tagged β subunit or control (tag only) DNA at a 2:1:1 ratio. DRG neurons that were positive for 1.8shRNA (indicated by dsRed fluorescence) and β subunit expression (indicated by Turquoise or Venus fluorescence) were selected for whole cell patch clamp. In the cells expressing Nav1.6r that were used in the final voltage clamp analysis, the peak recombinant current amplitude averaged 21.2 ± 1.7 nA (n=94). Cells that expressed Nav β 4 or Nav β 2 localized only to intracellular compartments (based on fluorescence localization) were excluded. Cells with

residual Nav1.8 current greater than 3% of the peak current of Nav1.6r were excluded. Nav1.8 contamination can be determined for each individual cell expressing recombinant current by examining the voltage-dependence of steady-state fast inactivation. The midpoint of inactivation for Nav1.8 is much more depolarized compared to Nav1.6. The curve of the voltage-dependence of inactivation was used to determine absolute and relative amplitude for Nav1.8 and Nav1.6r (19). Whole cell patch clamp recordings in voltage clamp and current clamp mode were obtained 2-3.5 days after transfection. As an observational note, DRG neurons that were biolistically transfected were generally considered small diameter neurons based on their membrane capacitance ($14.9 \pm 0.6\text{pF}$, $n=123$).

Electrophysiology

Whole cell patch clamp recordings were conducted in voltage clamp or current clamp mode at room temperature ($\sim 22^{\circ}\text{C}$) using a HEKA EPC-10USB. Data were acquired on a Windows-based Intel 2 Core using Patchmaster program (version 2X65; HEKA Elektronik). Fire polished glass electrodes ($0.7\text{-}1.1\text{M}\Omega$) were fabricated using a P-97 puller (Sutter), and tips were coated with dental wax to minimize capacitive artifacts and enhance series resistance compensation. The offset potential was zeroed prior to seal formation. Capacitive transients were canceled using computer controlled circuitry; C-fast for pipette capacitance correction and C-slow for cell capacitance compensation. Voltage

errors were minimized by series resistance compensation >75%. Membrane currents were sampled at 20KHz and filtered online at 10KHz. Leak currents were linearly cancelled by P/-5 subtraction (pulse/number).

For voltage clamp recordings, the electrode solution consisted of 140mM CsF, 10mM NaCl, 1.1mM EGTA, and 10mM HEPES (adjusted to pH 7.3 with CsOH). The extracellular bathing solution contained 130mM NaCl, 30mM TEA chloride, 1mM MgCl₂, 3mM KCl, 1mM CaCl₂, 0.05mM CdCl₂, 10mM HEPES and 10mM D-glucose (adjusted pH 7.3 with NaOH). Recording solutions were adjusted using D-glucose to maintain physiological osmolarity values (310 mOsm for internal solution and 320 mOsm for external solution). Whole cell currents in voltage clamp mode were not recorded before 4 minutes after whole cell configuration for Nav1.6r isolation and before 2 minutes after whole cell configuration for endogenous sodium currents. Cells were held at a potential of -100mV.

Current-voltage (I/V) relationships were determined by steps of 50ms, from -100 to + 80mV, in 5mV increments. The voltage-dependence of activation (m_{∞}) was determined from sodium currents elicited with I/V protocol from voltages of -100mV to 0mV. Conductance (G) values were calculated at each test potential (V_m) using the following equation, $G = \frac{I}{(V_m - V_r)}$. V_r is the voltage at which the direction sodium influx reverses. The reversal potential was quantified for each neuron Goldman-Hodgkin-Katz equation (221). Data were then

normalized to the peak conductance, plotted as a function of voltage and fitted using single-phase Boltzmann distribution equation,

$$\frac{G}{G_{max}} = \left(\frac{1}{1 + e^{(V_m - V_{1/2})/k}} \right).$$

The midpoint voltage of activation ($V_{1/2}$) and slope

factor (k) were obtained for each cell.

Steady-state fast inactivation (h_{∞}) was assayed with 500ms pre-pulses from -130 to 5mV (in 5mV increments) followed by a 20ms test pulse to -20mV to assess channel availability. Currents at each pre-pulse were normalized to the peak current. Data of normalized currents as a function of voltage was fitted with

the single phase Boltzmann distribution, $\frac{I}{I_{max}} = \left(\frac{1}{1 + e^{(V_m - V_{1/2})/k}} \right)$, from which the

midpoint voltage of inactivation ($V_{1/2}$) and slope factor (k) were obtained for each cell. V_m corresponded to the prepulse voltage. Additionally, current densities were estimated for each individual recording by dividing the peak transient currents obtained from h_{∞} by the membrane capacitance. For endogenous current recordings, the fast component of the sodium currents was isolated by pre-pulse subtraction of the slow component as previously described in (88).

Current densities were estimated for each individual recording by dividing the peak transient currents obtained from h_{∞} protocol by the membrane capacitance. Comparison of values for inactivation, activation and current density were done using ANOVA and post-hoc Bonferroni test.

For current clamp recordings, the goal was to study the activity mediated by Nav1.6r under control and Nav β 4 overexpression conditions. Thus, transfected Nav1.6r was isolated by silencing the function of other voltage-gated sodium channels with TTX and Nav1.8-shRNA as described above. The pipette solution contained 140mM KCl, 0.5mM EGTA, 5mM HEPES and 3mM Mg-ATP (adjusted pH 7.3 with KOH). The extracellular solution contained 140mM NaCl, 3mM KCl, 2mM MgCl₂, 2mM CaCl₂, 10mM HEPES and 500nM TTX (adjusted pH 7.3 with NaOH). Recording solutions were adjusted using D-glucose to maintain physiological osmolarity values. Recording were obtained from the DRG neuron resting potential. No current was injected to hold the cell at a specific voltage. A cell was classified as spontaneously active if spontaneous firing was maintained for 3 or more minutes. DRG neurons that were not spontaneously active were examined for evoked activity with a series of current injections from -200pA to 1.2nA in 100pA increments. For evoked activity, the maximum number of action potentials elicited from each cell was determined as the maximum action potentials elicited from current injections from 0 to 1.2nA. For non-spontaneous neurons rheobase was determined as the minimum current injection needed to elicit an action potential response and input resistance (R) was estimated from the membrane potential (ΔV) change at -200pA current injection (I) using the equation: $V=IR$.

Comparison of current clamp parameters examined was done using Student t-test. Voltage and current clamp data were analyzed using Origin

(version 8, OriginLab), Fitmaster (v2X65, HEKA Elektronik), Excel (Microsoft) and Prism (version 6, GraphPad) software programs.

Resurgent currents and analysis

Cells were assayed with a step protocol that initially depolarized the membrane to +30mV for 20ms from the holding potential, followed by repolarizing voltage steps from +15mV to -85 for 100ms in -5mV increments to test for resurgent currents; cells were then returned to their holding potential. Resurgent currents display unique characteristics of slow onset and slow decay along with a non-monotonic I/V relationship. Currents that did not meet these characteristics were classified as negative for resurgent currents. Based on these criteria, the percentage of DRG that were positive/negative for detectable resurgent current was quantified for each condition. The Chi-square test (X^2 test) was then used to compare distributions between conditions. Resurgent current amplitudes were measured from the leak-subtracted baseline to the peak after 3.0ms into the repolarizing pulse to avoid contamination from tail currents. Relative resurgent currents were calculated by dividing peak resurgent current by the peak transient current and expressed as a percentage of the peak transient current. The peak transient current was determined as the peak from the h_{∞} protocol. For endogenous resurgent current recordings, the peak transient of the h_{∞} protocol was determined after subtraction of the slow component using pre-pulse subtraction (88). For population data, relative resurgent currents were

plotted as a function of voltage. Student's t test was used to examine the statistical significance of relative resurgent current amplitude between groups.

Results

Nav β 4 and Nav1.6 expression are correlated in DRG neurons.

The goal of our study was to determine if Nav β 4 regulates fast resurgent currents in DRG neurons. Therefore, we examined the expression pattern of Nav β 4 in rat DRG neurons and its correlation with Nav1.6 expression pattern. Immunostaining of DRG neurons in dissociated cultures shows that the Nav β 4 signal is present in all size classes. However, the mean intensity of staining was three-fold higher in medium to large diameter neurons than in small diameter neurons (mean intensity $p < 0.0001$: medium to large diameter, 49.5 ± 2 Arbitrary Units (AU), $n=260$; small diameter 17.4 ± 0.5 AU, $n=557$). These medium to large diameter neurons, with estimated cross sectional area $>400 \mu\text{m}^2$, most likely give rise to A δ and A β fibers. Our results are consistent with previous studies, which found Nav β 4 mRNA levels to be higher in medium to large diameter neurons relative to small diameter neurons (23, 138). Similarly, the Nav1.6 signal is observed in all size classes but exhibits more pronounced immunostaining in medium to large diameter neurons, consistent with previous observations (13, 222). The mean intensity of staining was more than two-fold higher in medium to large diameter neurons than in small diameter neurons (mean intensity

$p < 0.0001$: medium to large diameter, $62.5 \pm 2\text{AU}$, $n=260$; small diameter $26.94 \pm 1\text{AU}$, $n=557$). Representative images are shown in Figure 6A-C. Co-expression of the two signals (Nav β 4-green and Nav1.6-red) in neurons was quantified using the Pearson correlation coefficient method. Using this approach, we found that medium to large diameter neurons have a stronger correlation between Nav1.6 and Nav β 4 expression than small diameter neurons (Figure 6D-E, Pearson correlation coefficient $p < 0.0001$: medium to large diameter, 0.81 ± 0.01 , $n=344$; small diameter, 0.18 ± 0.02 , $n=348$).

Figure 6: Expression of Nav1.6 and Nav β 4 in DRG neurons. Examples of immunocytochemical staining of Nav β 4 and Nav1.6 in primary cultured DRG neurons are shown in **A** and **B**. Nav β 4 signal is shown in green and Nav1.6 signal is shown in red with corresponding brightfield (DIC) image shown in **C**. Merged image (**D**) shows that some DRG neurons but not all express both Nav1.6 and Nav β 4. **E**, Strong co-expression of Nav1.6 and Nav β 4 signal is mainly observed in medium to large diameter neurons (>400 μm^2 , $n=344$), but not small diameter neurons (<400 μm^2 , $n=347$) as indicated by the Pearson correlation coefficient. Asterisks (****) represent $p < 0.0001$ obtained from Student's t-test. Scale bar 50 μm .

Navβ4 knockdown reduces resurgent current generation.

We next investigated if Navβ4 functionally regulates endogenous fast resurgent current generation in DRG neurons. In order to address this question we used an *in vivo* knockdown approach (223). Animals received localized injections (near L4 and L5 DRG) of Navβ4-siRNAs (β4-siRNA) or non-targeting control siRNAs (n.t. control) mixed with the transfection reagent JetPEI (see Methods). Three days post injection, DRG neurons were grown in culture. After 16-36 hours in culture, DRG neurons were examined by immunocytochemistry to verify knockdown and subjected to whole cell patch clamp recordings to assess sodium current properties. Representative images of Navβ4 staining in n.t. control and β4-siRNA groups are shown in Figure 7A-B. Navβ4 levels were reduced in the β4-siRNA group by approximately 50% compared to n.t. control (Figure 7C, corrected total cell fluorescence $p < 0.0001$: β4siRNA, $1.3 \pm 0.10 \times 10^7$ AU, $n=352$; n.t. control group, $2.5 \pm 0.15 \times 10^7$ AU, $n=264$).

Figure 7: In vivo knockdown decreases Navβ4 expression levels. Representative images of immunocytochemical staining of Navβ4 in primary cultured DRG neurons from rats injected with non-targeting siRNA (n.t. control, **A**) or Navβ4-siRNA (β4-siRNA, **B**) 72 hours post injection. **C**, Corrected Total Cell Fluorescence (CTCF) is significantly decreased in DRG neurons from rats injected with β4-siRNA ($n=352$ from 3 rats, $p < 0.0001$) compared with n.t. control ($n=264$ from 3 rats). Scale bar 50μm. Asterisks (****) represent $p < 0.0001$ obtained from Student's t-test.

Endogenous sodium currents were recorded from medium to large diameter DRG neurons cultured from rats treated with $\beta 4$ -siRNA or n.t. control. Small diameter neurons were excluded because these neurons do not endogenously generate fast resurgent current under normal conditions (23, 27), possibly reflecting the weak correlation of Nav1.6 and Nav $\beta 4$ expression (Figure 5). Cell size was assessed by measurement of total membrane capacitance. In the 39 cells examined, the average cell capacitance was 60.2 ± 2.9 pF and cell capacitance was not different between the groups. Capacitance is linearly correlated to the surface area of cell (224). We estimate that the average cell diameter was $60.2 \mu\text{m}$, assuming a spherical morphology (34, 225). Therefore, the DRG neurons examined were considered as part of the large diameter population (226).

In order to determine relative changes in fast resurgent currents (which are TTXS) and exclude potential effects due to changes in TTXS channel density, resurgent current amplitudes were normalized to the TTXS peak transient current amplitudes. Resurgent currents were examined using a two-step pulse protocol described in the Methods section. Figures 8A and 8B show representative traces of endogenous fast resurgent current obtained from each group. $\beta 4$ -siRNA treatment significantly reduced the fraction of neurons positive for the fast resurgent current relative to n.t. control (Figure 8C, χ^2 test, $p < 0.05$). In the $\beta 4$ -siRNA group, 7 out of 20 neurons (35%) generated fast resurgent current, whereas in the n.t. control group, 15 out of 19 (79%) neurons exhibited

fast resurgent current. Moreover, the average amplitude of the fast resurgent current (expressed as a percentage of peak transient TTXS current) was significantly decreased in the $\beta 4$ -siRNA group compared to control (Figure 8D, n.t. control $1.79 \pm 0.36\%$, $n=19$; $\beta 4$ siRNA $0.60 \pm 0.28\%$, $n=20$).

Figure 8: Nav $\beta 4$ knockdown reduces endogenous fast resurgent current. Representative traces of endogenous fast resurgent currents obtained from medium to large diameter DRG neurons cultured from rats injected with n.t. control (A) or $\beta 4$ siRNA (B). Peak resurgent current traces are highlighted with black (n.t. control) and brown ($\beta 4$ siRNA). C, Compared with n.t. control, $\beta 4$ siRNA significantly decreased the percentage of DRG neurons that generated resurgent currents ($p < 0.0005$, χ^2 test). D, Compared to control (black squares, $n=19$), Nav $\beta 4$ knockdown (brown diamonds, $n=20$) significantly decreased resurgent current amplitude in a range of voltages. (*, $p < 0.05$ obtained from Student's t-test). Summary data are mean \pm SEM.

Nav $\beta 4$ may also alter the voltage-dependence of activation and inactivation of VGSCs (135). For example, in cerebellar granule neurons Nav $\beta 4$ knockdown shifted the voltage-dependence of inactivation to more negative potentials, whereas, activation was unchanged (197). In contrast, in heterologous expression systems, Nav $\beta 4$ co-expression shifts the voltage-dependence of

activation to negative potentials but no change in inactivation is observed (198, 200, 227). Modulation by Nav β 4 seems to be cell background specific. In the endogenous sodium current recordings obtained, activation was not studied due to contamination with TTXR currents that cannot be readily subtracted. However, using pre-pulse subtraction, we isolated the TTXS component of the sodium currents recorded with the steady-state inactivation protocol and compared the voltage-dependence of inactivation between groups. Nav β 4 knockdown slightly shifted the voltage-dependence of inactivation to more hyperpolarized potentials. This apparent shift did not quite reach significance (Figure 9A. midpoint voltage of inactivation, $p=0.052$; n.t. control $-67.7 \pm 2.4\text{mV}$, $n=18$; β 4-siRNA $-73.6 \pm 2.6\text{mV}$, $n=20$). The peak current density of transient currents, which can contain both fast (TTXS) and slow (TTXR) sodium currents, was not significantly different. However, when the TTXS component was isolated by prepulse subtraction, there was a 32% reduction in the peak current density with β 4-siRNA treatment (Figure 9B-C).

Figure 9: Inactivation properties and peak current of endogenous sodium current in control and β 4-siRNA groups. **A**, Voltage-dependence of steady-state inactivation in β 4-siRNA group (brown diamonds) and n.t. control (black squares). **B**, Total peak current density is not different between non-targeting control ($n=19$) and β 4-siRNA ($n=20$). **C**, After pre-pulse subtraction the (TTXS) fast component was isolated from total peak current density. TTXS peak current density was significantly decreased in β 4-siRNA relative to n.t. control (*, $p<0.05$ obtained from Student's t-test). Summary data are mean \pm SEM.

Nav β 4 increases Nav1.6r resurgent currents whereas Nav β 2 does not.

Using recombinant expression in DRG neurons grown in culture, we studied the effects of overexpression of Nav β 4 and Nav β 2 on Nav1.6 mediated fast resurgent currents. Nav β 4 is most homologous to Nav β 2, with 35% identity (198). While they are structurally similar, Nav β 2 has been proposed to lack the appropriate properties to enable open channel block (180, 199). Therefore, we hypothesized that Nav β 4 overexpression would increase fast resurgent current, whereas Nav β 2 would not. Interestingly, both subunits contain a free cysteine that is likely to form a disulfide bond with the α subunit (228-230). While it is not known if Nav β 2 and Nav β 4 compete for the same cysteine on the α subunit, if they do compete, then Nav β 2 would be predicted to decrease fast resurgent current.

Dissociated DRG neuronal cultures were co-transfected with recombinant human Nav1.6 and either wild-type (WT) Nav β 4 or Nav β 2. We used a Nav1.6 construct (Nav1.6r) that has been mutated to be resistant to TTX (213). This allows 500nM TTX to be used to block endogenous TTXS currents without blocking Nav1.6r currents, enabling pharmacological isolation of Nav1.6r mediated fast resurgent currents (19) (see Methods section). β subunit constructs were tagged with a fluorescent protein (Venus or Turquoise) at the C-terminus to verify expression. As a control, Nav1.6r was co-expressed with fluorescent protein (corresponding to the tag). In addition, Nav1.8 was knocked

down with co-transfection of a Nav1.8 shRNA-IRES-dsRED construct to minimize contamination by Nav1.8 currents (19, 218) (see Methods section). Whole cell patch clamp recordings were obtained 2-3.5 days post-transfection.

Representative traces of Nav1.6r resurgent currents recorded with co-transfection of control (fluorescent tag), Nav β 4-WT and Nav β 2-WT are shown in Figure 10A-C. The percentage of transfected cells exhibiting fast resurgent current increased significantly with Nav β 4-WT overexpression (Figure 10D, χ^2 -test, $p < 0.0001$). For the Nav β 4-WT group, 24 out of 24 cells (100%) generated fast resurgent current, whereas in the control group 20 out of 36 cells (56%) exhibited identifiable fast resurgent currents. No difference in resurgent current frequency was observed between Nav β 2 (7 out of 17 cells, 41%) and control. Overexpression of Nav β 4-WT also resulted in a three-fold increase in fast resurgent current amplitude relative to control (Figure 10E, $p < 0.0001$; control $0.84 \pm 0.2\%$, $n=36$; Nav β 4-WT $2.94 \pm 0.3\%$, $n=24$). In contrast, there was no difference in fast resurgent current amplitude between the Nav β 2-WT group and control ($0.7 \pm 0.2\%$, $n=17$).

Nav1.6r transient current recordings were analyzed for potential alterations in activation, steady-state fast inactivation and current density. Overexpression of Nav β 4-WT caused a significant decrease in current density, a depolarizing shift in inactivation and no change in activation relative to control. T

Nav β 2-WT overexpression only altered the slope of the voltage-dependence of activation and inactivation relative to control (Figure 11 and Table 2).

Figure 10: Overexpression of Nav β 4-WT of DRG neuron increases Nav1.6r resurgent currents whereas Nav β 2-WT does not. DRG neurons were transfected with Nav1.6r and Nav β 4-WT, Nav β 2-WT or fluorescent protein tag (control). β subunits were tagged with fluorescent protein to monitor expression. Representative traces were obtained from transfected DRG neurons and peak resurgent currents are highlighted for control (**A**, black), Nav β 4-WT (**B**, blue), and Nav β 2-WT (**C**, green). **D**, Overexpression of Nav β 4-WT significantly increased the percentage of DRG neurons that generated resurgent current compared to control ($p < 0.0001$, χ^2 test). The percentage of DRG neurons that generated resurgent currents was not different between Nav β 2-WT and control groups. **E**, Compared to control (black circles, $n=36$), overexpression of Nav β 4-WT (blue squares, $n=24$) increased resurgent current amplitude. Nav β 2-WT (green triangles, $n=17$) did not alter resurgent current amplitude relative to control. Note that resurgent currents were normalized to peak transient currents and plotted as a function of voltage. Summary data are mean \pm SEM.

Figure 11: Biophysical properties of Nav1.6r transient current with β subunit co-expression. Representative traces of Nav1.6r transient current recordings with co-expression of fluorescent tag (control, **A**, black circles), Nav β 4-WT (**B**, blue squares), Nav β 2-WT (**C**, green triangles) and Nav β 4-Mt (**D**, purple diamonds). **E**, Nav β 4-WT and Nav β 4-Mt co-expression significantly shift the voltage-dependence of steady-state fast inactivation to depolarizing potentials relative to control whereas Nav β 2-WT does not. Nav β 4-Mt shifted significantly the voltage-dependence of inactivation to more depolarized potentials relative to Nav β 4-WT. **F**, Nav β 4-Mt co-expression shifts the voltage-dependence of activation of Nav1.6r to depolarized potentials relative to control and Nav β 4-WT. Nav β 2 and Nav β 4-WT do not significantly alter the voltage-dependence of activation relative to control. Table 1 contains the values for Boltzmann fit for steady-state fast inactivation, activation and corresponding comparisons.

Navβ4 C-terminus is important for the regulation of Nav1.6r resurgent currents

We next investigated if the C-terminal region proposed to act as an open channel blocker (Amino Acids: 184-203; β4 peptide) (180, 183, 197) was important for Navβ4-WT positive regulation of fast resurgent currents in DRG neurons. While the β4-peptide can recapitulate resurgent currents in various cell types (199), the role of this region has not been studied in full length Navβ4. Therefore, we generated a mutant Navβ4 (Navβ4-Mt) in which five lysine residues at positions 192-193 and 197-199 were converted to alanine (Figure 12A). These residues were chosen because the positive charges at these positions are highly conserved between Navβ4 of different species and have been shown to be important for β4-peptide open channel blocker activity (180, 199). Based on peptide studies, we predicted that the C-terminus of Navβ4-Mt would not be able to bind to the sodium channel pore and therefore would not facilitate the generation of fast resurgent current.

In contrast to Navβ4-WT, overexpression of Navβ4-Mt did not enhance fast resurgent current generation. Figure 12B, shows a comparison of representative traces of Nav1.6r resurgent currents recorded after co-transfection of Navβ4-Mt, control (fluorescent tag) and Navβ4-WT. Overexpression of Navβ4-Mt decreased the percentage of resurgent current positive neurons (Figure 12C: % of fast resurgent current positive neurons, Navβ4-Mt, 31%, χ^2 -test, $p < 0.0001$) relative to Navβ4-WT group but was not significantly different from control

($p=0.053$). Similarly, fast resurgent current amplitude was significantly decreased relative to Nav β 4-WT (Figure 12D, $p<0.0001$; Nav β 4-Mt $0.61 \pm 0.3\%$, $n=16$) but was not significantly different compared to control. Surprisingly, analysis of transient current recordings revealed that Nav β 4-Mt overexpression shifted the voltage-dependence of steady-state fast inactivation and activation to positive potentials relative to Nav β 4-WT and control (Figure 11 and Table 2).

Figure 12: Nav β 4 C-terminus is important for positive regulation of resurgent currents. **A**, Illustration of Nav β 4 subunit, which consists of an extracellular immunoglobulin-like domain, a single transmembrane domain, and a cytoplasmic domain. The cytoplasmic domain contains the β 4 peptide sequence (amino acids 183-203) proposed to mediate resurgent currents. **Inset**, highlights the 20 amino acids segment sequence of the cytoplasmic domain of Nav β 4 corresponding to residues 183-203 of the rat protein. Red lettering indicates five lysine residues corresponding to Nav β 4-WT (β 4-WT) sequence in C-terminal region that were neutralized to alanine to generate a predicted inactive form of Nav β 4 (Nav β 4-Mt). **B**, Representative trace obtained from transfected DRG neurons with Nav1.6r and Nav β 4-Mt. Nav β 4-Mt peak resurgent current is highlighted in purple. For comparison representative trace of peak resurgent current obtained from Nav β 4-WT group is highlighted in blue and control is highlighted in black. **C**, Overexpression of Nav β 4-Mt significantly decreased the percentage of DRG neurons that generated resurgent current compared to Nav β 4-WT ($p<0.0001$, χ^2 test) but not significantly different to control. **D**, Resurgent current amplitude in Nav β 4-Mt group (purple circles, $n=16$) was significantly decreased compared to Nav β 4-WT (blue line) but not different to control. Note that resurgent currents were normalized to peak transient currents and plotted as a function of voltage. Nav β 4-WT and control data are plotted as a line of the average for reference. Nav β 4-Mt summary data are mean \pm SEM.

Navβ4 expression increases excitability of DRG neurons

Our data demonstrate that Navβ4-WT overexpression increased Nav1.6r resurgent currents DRG neurons. Therefore, we used this as an opportunity to study the impact of increased fast resurgent current on DRG neuronal excitability. DRG neurons were co-transfected with Nav1.6r and either the fluorescent tag (control) or Navβ4-WT. Current clamp experiments were conducted on transfected neurons using Nav1.8 shRNA and TTX to block endogenous sodium currents. This approach allowed us to examine Nav1.6r dependent neuronal excitability. Spontaneous activity was observed in the Navβ4-WT group but not in the control neurons (Figure 13A-B). Four out of 15 cells (27%) transfected with Navβ4-WT were spontaneously active while zero of 15 control cells (0%) were spontaneously active. Thus, overexpression of Navβ4-WT significantly increased spontaneous activity (χ^2 test, $p < 0.05$). In cells that did not exhibit spontaneous activity, neuronal excitability was examined by a series of 1s current injections (-200pA up to 1.2nA in 100pA increments) from their resting membrane potentials. Representative membrane responses to current injections (evoked activity at rheobase) in control and Navβ4-WT transfected neurons are shown in Figure 13C. Navβ4 overexpression significantly increased the maximum number of evoked action potentials (Figure 13D: Navβ4-WT 4.5 ± 1.8 , $n=11$; control 1.2 ± 0.1 , $n=15$, $p < 0.05$). The maximum number of evoked action potentials was defined as the maximum number of action potentials elicited at a given current injection from -200pA to 1.2nA for each cell. The

number of evoked action potentials was also significantly greater with Nav β 4 overexpression when measured specifically at rheobase, and at 2X and 3X rheobase compared to control (Figure 14). In cells that we examined for evoked activity no significant change was observed in resting membrane potential, input resistance or rheobase (Table 3).

Figure 13: Overexpression of Nav β 4-WT increases excitability of DRG neurons. DRG neurons co-transfected with Nav1.6r and fluorescent probe tag (control) or Nav β 4-WT were examined under current clamp conditions. 500nM TTX was included in the bath solution to block endogenous TTXS channels and Nav1.8 was knocked-down with shRNA. **A**, Representative traces of spontaneous activity recorded in control (left panel) and Nav β 4 (right panel) groups. **B**, Overexpression of Nav β 4 (n=14) increased the percentage of neurons that were spontaneously active (p<0.05, Fisher's exact test) compared to control (n=15). Cells that were not spontaneously active were examined for evoked activity. A series of one second depolarizing current steps (0pA up 1.2nA in 100pA increments) were injected into transfected DRG neurons from their resting membrane potentials. **C**, Representative membrane responses to current injections at rheobase in control (left panel) and Nav β 4-WT (right panel). **D**, Compared with control, Nav β 4-WT overexpression significantly increased the maximum number of evoked action potential. The maximum number of evoked action potentials was defined as the maximum number of action potentials elicited at a give current injection from -200pA to 1.2nA for each cell. Data are mean \pm SEM. *p<0.05, Student's t-test

Figure 14: Navβ4 increased evoked action potentials in response to a range of stimuli intensities. Non-spontaneous cells were stimulated with 1X, 2X and 3X rheobase current injections. Compared to control (black, n=15), Navβ4-WT (blue, n=11) overexpression significantly increased the maximum number of evoked action potential at 1X, 2X and 3X rheobase. Data are mean ± SEM. *p<0.05, Student's t-test

Discussion

In this study we tested the hypothesis that Nav β 4 is key to the generation of fast resurgent sodium currents in DRG sensory neurons. Five principle findings support the conclusion that Nav β 4 is the primary open channel blocker underlying sensory neuron fast resurgent currents. First, Nav β 4 antibody staining is highly correlated with Nav1.6 antibody staining, and this relationship is predominantly observed in medium to large neurons where endogenous fast resurgent currents are typically observed. Second, Nav β 4 knockdown substantially attenuates endogenous fast resurgent sodium currents in medium to large diameter sensory neurons. Third, co-expressing Nav β 4 with recombinant Nav1.6r channels in cultured sensory neurons resulted in a 3-fold increase in Nav1.6r resurgent current amplitude relative to control. Fourth, co-expressing the closely related Nav β 2 with recombinant Nav1.6r channels in cultured sensory neurons did not increase Nav1.6r resurgent current amplitude relative to control. Fifth, co-expressing a mutant Nav β 4 with recombinant Nav1.6r channels in cultured sensory neurons also did not increase Nav1.6r resurgent current amplitude relative to control, although other channel properties were altered. In addition, co-expressing the wild-type Nav β 4 with recombinant Nav1.6r channels in cultured sensory neurons substantially increased neuronal excitability, indicating that resurgent sodium currents are important regulators of sensory neuron action potential activity.

Sensory neurons express multiple isoforms of the voltage-gated sodium channel, including TTXS and TTXR channels. In a previous study, fast resurgent sodium currents were observed in 44% of mouse sensory neurons with larger diameter somas, but were not observed in neurons from Nav1.6-knockout mice (27). In the current study, we observed a high degree of association between Nav1.6 and Nav β 4 antibody staining in medium to large diameter rat neurons, 79% of which generated fast resurgent currents. Although the immunocytochemistry we performed demonstrates that expression of Nav1.6 and Nav β 4 is highly correlated in medium to large diameter neurons, it cannot determine if these subunits interact. All of the neurons co-transfected with Nav β 4 and Nav1.6r channels generated fast resurgent sodium currents, supporting the hypothesis that Nav1.6 and Nav β 4 interact and suggesting that expression of Nav β 4 might be sufficient for fast resurgent sodium current generation in DRG sensory neurons expressing Nav1.6. However, it is important to point out that the neurons typically transfected and recorded from in our sensory neuron expression system experiments are almost always small diameter sensory neurons; larger diameter neurons do not survive the culturing and transfection procedure very well. It is possible, and even likely, that in some neuronal populations there are other factors that limit the ability of Nav β 4 to generate resurgent sodium currents (176).

Nav β 2 co-expressed with Nav1.6r did not result in increased resurgent sodium currents. Although the percentage of transfected Nav β 2 cells that

generated fast resurgent sodium currents seemed slightly lower than that of control neurons, this difference was not significant (nor was the resurgent current amplitude significantly different). Both Nav β 4 and Nav β 2 are thought to form a disulfide linkage with sodium channel α subunits and because of this it has been proposed that a given α subunit may associate with either Nav β 4 or Nav β 2, but not both (231). Although Nav β 2 overexpression did not significantly reduce fast resurgent current amplitude, this does not necessarily indicate that Nav β 4 and Nav β 2 can simultaneously associate with α subunits. One possibility is that Nav β 2 may poorly associate with Nav1.6r channels. Another possibility is that the expression of Nav β 2 was not high enough to compete with endogenous Nav β 4 (although expression of Nav β 2 was visually confirmed with a fluorescent tag). Interestingly, expression of a mutant Nav β 4 also did not reduce the baseline resurgent current amplitude significantly. However, this construct shifted the voltage-dependence of Nav1.6r channel activation and inactivation, indicating it does associate with Nav1.6r channels. This raises the possibility that there might be another open channel blocker, at least in small diameter sensory neurons, that could contribute to fast resurgent current generation independent of Nav β 4 association.

Although Nav1.6 appears to be the predominant generator of fast TTXS resurgent currents in sensory neurons, it is not the only isoform that can generate resurgent sodium currents (19, 232, 233). Nav1.7 is not an efficient generator of resurgent sodium currents (19) despite having similar kinetics of open-state

inactivation to Nav1.6 (212), but mutations identified in patients with PEPD can substantially increase Nav1.7 resurgent currents (19, 24, 183). Nav1.8 channels can also generate resurgent sodium currents in DRG sensory neurons (25). Nav1.8 resurgent currents are much slower and are resistant to TTX. Although we did not examine slow TTXR resurgent currents in this study, it is likely that Nav β 4 plays an important role in these currents, as inclusion of a 14-mer peptide corresponding to the proximal portion of the Nav β 4 cytoplasmic C-terminus (the first 14 amino acids highlighted in Figure 12A) significantly enhanced slow TTXR resurgent currents in DRG neurons (25).

Resurgent currents are likely to be an important determinant of sensory neuron excitability. Overexpression of Nav β 4 with Nav1.6r substantially enhanced both spontaneous and evoked firing in sensory neurons compared to neurons transfected with Nav1.6r and the fluorescent tag. It is important to note that the activity of endogenous sodium channels was blocked in these experiments, so the increased excitability most likely reflects enhanced Nav1.6r activity. Overexpression of wild-type Nav β 4 increased resurgent current amplitude by 3-fold and shifted the voltage-dependence of inactivation by +4 mV. Based on the small magnitude of the shift in the voltage-dependence of inactivation, we predict that the 3-fold increase in resurgent currents was the major factor in the increased evoked action potential firing that we observed. Although the mutant Nav β 4 did not enhance resurgent currents, it induced a pronounced shift in activation that precluded its use in the current clamp

experiments. The increased spontaneous activity observed with overexpression of wild-type Nav β 4 is intriguing, but as resurgent currents are predicted to have their pronounced impact during the repolarization phase of action potentials, it is not entirely clear how the increased spontaneous activity might result from enhanced resurgent current activity. One possibility is that, in addition to enhancing resurgent currents, Nav β 4 might also increase persistent sodium currents associated with Nav1.6. Although we did not examine persistent currents in this set of experiments, our work with Nav β 4 knockdown in the localized inflammation of the DRG pain model (see Part II) suggests that indeed Nav β 4 plays a role in modulating persistent currents. Alternatively, Nav β 4 may alter other targets that contribute to spontaneous activity. For example, Nav β 1 has been reported to modulate voltage-gated potassium channels in CNS neurons (234, 235). Voltage gated potassium channels are major contributors to the action potential waveform and can thus substantially modulate the excitability of neurons (236). Although we did not see a significant change in resting membrane potential or input resistance in non-spontaneously active cells, it is possible that spontaneously active neurons did exhibit these changes. Further studies would be needed to elucidate if Nav β 4 modulates potassium channels in DRG neurons.

Enhanced Nav1.6 resurgent currents have been proposed to underlie the sensory neuronal excitability associated with oxaliplatin and sea anemone toxin ATX-II induced pain sensations (23, 26). Furthermore, inflammatory mediators

applied to cultured DRG neurons increased both TTXS and TTXR resurgent currents, suggesting that resurgent currents can also play a role in inflammatory pain (25). Inflammatory mediators can increase the activity of multiple kinases and phosphorylation is known to enhance resurgent current generation (24, 237). It will be interesting to determine if chronic oxaliplatin treatment and/or chronic inflammation can induce an upregulation of Nav β 4 in sensory neurons.

Nav1.6 and Nav β 4 expression is highly correlated in medium to large diameter neurons. Nav β 4 overexpression enhanced resurgent currents and excitability, whereas knockdown or expression of mutant Nav β 4 decreased resurgent current generation. Overall, our data suggest that Nav β 4 is a major contributor to fast resurgent current generation, particularly in larger diameter neurons. Although it is not clear what sensory modalities are most impacted by fast resurgent sodium currents, Nav β 4 is likely to be an important determinant of sensory neuronal hyperexcitability and thus could represent an important target for the development of novel therapeutics.

PART II: UPREGULATION OF THE SODIUM CHANNEL $\text{Na}_v\beta 4$ SUBUNIT AND ITS CONTRIBUTIONS TO MECHANICAL HYPERSENSITIVITY AND NEURONAL HYPEREXCITABILITY IN A RAT MODEL OF RADICULAR PAIN INDUCED BY LOCAL DRG INFLAMMATION

Special Acknowledgement: This study was a collaboration between Dr. Jun-Ming Zhang's laboratory at University of Cincinnati and Dr. Theodore Cummins' laboratory at Indiana University. Dr. Judith Strong and Dr. Wenrui Xie carried out the surgical procedures, behavioral tests, immunohistochemical assays, Western blotting and microelectrode experiments. C Barbosa and Dr. Zhiyong Tan carried out the surgical procedures, patch clamp experiments, immunocytochemical assays and corroborated mechanical hypersensitivity effects of LID and $\text{Nav}\beta 4$ knockdown. The results were published in PAIN. Dr. Strong produced the initial draft of the manuscript, which was subsequently edited and revised by all collaborators. This part of the dissertation is adapted from the published study.

Summary

High frequency spontaneous firing in myelinated sensory neurons plays a key role in initiating pain behaviors in several different models, including a radicular model in which the rat lumbar DRG are locally inflamed. Sodium channel isoform $\text{Nav}1.6$, the main carrier of fast resurgent currents, contributes to pain behaviors and spontaneous activity in this radicular pain model. Resurgent

currents are generated by an alternate mechanism of inactivation that blocks the channel in the open conformation. As the blocking particle disengages during membrane repolarization, atypical sodium influx is generated and may promote high frequency firing. Our previous study suggests the regulatory Nav β 4 subunit is likely the endogenous blocker in DRG neurons. Therefore, we used in-vivo siRNA mediated knockdown of Nav β 4 to examine its role in this radicular pain model induced by localized inflammation. Nav β 4 siRNA, but not control siRNA reduced persistent mechanical hypersensitivity induced by inflammation. Microelectrode recordings in isolated whole DRG showed that Nav β 4-siRNA blocked inflammation induced increases in spontaneous activity of A β neurons, reduced repetitive firing and attenuated other measures of excitability. Nav β 4 was preferentially expressed in larger diameter cells; inflammation of the DRG increased Nav β 4 expression and this was reversed by Nav β 4-siRNA, based on immunohistochemistry and Western blotting. Patch clamp recordings of TTXS currents in acutely cultured medium diameter DRG neurons showed that DRG inflammation increased transient and fast resurgent sodium currents; effects reduced by Nav β 4-siRNA. Based on our findings, Nav β 4 may prove to be a novel target for pain conditions that depend on hyperexcitability of myelinated neurons expressing Nav1.6.

Materials and Methods

Procedure for in vivo injection of siRNA near the DRG

The experimental protocol was approved by the Institutional Animal Care and Use Committees of the University of Cincinnati and Indiana University School of Medicine. Experiments were conducted in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Adult Sprague Dawley rats (Harlan, Indianapolis, USA) of both sexes were used as indicated.

siRNAs directed against rat Nav β 4 subunit (Scn4b; gene ID 315611) and non-targeting control were designed by and purchased from Dharmacon/ThermoFisher (Lafayette, CO). The Nav β 4-siRNA was siGENOME™ siRNA consisting of a “smartpool” of four different siRNA constructs combined into one reagent. Catalog numbers were M-101002-01 (directed against Nav β 4) and D-001210-02 (non-targeting control directed against firefly luciferase, screened to have minimal off-target effects and at least 4 mismatches with all known human, mouse and rat genes according to the manufacturer). The sequences for the Nav β 4-siRNA were: AAACAACUCUGCUACGAUC, GCAAUACUCAGGCGAGAUG, UCCAAGUGGUUGAUAAAUU and GGAUCGUGAAGAAUGAUAA. Aliquots of 3 μ L containing 80pmoles of siRNA mixed with cationic linear polyethylenimine (PEI) based transfection reagent (“in

vivo JetPEI”, Polyplus Transfection, distributed by WVR Scientific, USA) at a nitrogen/phosphorus ratio of 8 were injected near each L4 and L5 DRG on one side, through a small glass needle inserted close to the DRG through a small hole cut into the overlying membrane, as previously described (223). The siRNA was injected just prior to DRG inflammation in experiments using both procedures.

The surgical procedures for local inflammation of the DRG (LID) were performed as previously described (238). The L5 DRG was inflamed by depositing the immune activator zymosan (2mg/mL, 10 μ L, in incomplete Freund’s adjuvant) over the L5 DRG via a small needle inserted into the L5 intervertebral foramen. For animals used for electrophysiological and microscopy experiments the L4 DRG was also inflamed. Naive or Sham operated animals were used as a control. Sham operated animal underwent the above procedure with the exception of zymosan injection.

Behavioral testing

Mechanical sensitivity was tested by applying a series of von Frey filaments to the heel region of the paws, using the up-and-down method (239). A cutoff value of 15 grams was assigned to animals that did not respond to the highest filament strength. A wisp of cotton pulled up from, but still attached to a cotton swab was stroked mediolaterally across the plantar surface of the

hindpaws to score the presence or absence of a brisk withdrawal response to a normally innocuous mechanical stimulus (light touch-evoked tactile allodynia). This stimulus does not evoke a response in normal animals. Cold sensitivity was scored as withdrawal responses to a drop of acetone applied to the ventral surface of the hind paw. When observed, responses to acetone or light brush strokes consisted of several rapid flicks of the paw and/or licking and shaking of the paw; walking movements were not scored as positive responses. Hypersensitivity to thermal (heat) stimuli was not examined because we have previously observed that this behavior is minimally affected in this model (116). True blinding of the experimenter to the siRNA type injected was found to be difficult due to the large effect size; however, a subset of behavioral experiments was conducted with the experimenter blind to the siRNA type, as indicated.

Electrophysiology

Microelectrode current clamp recordings in whole DRG: Intracellular recording in current clamp mode was performed at 36-37°C using microelectrodes on sensory neurons near the dorsal surface of an acutely isolated whole DRG preparation, as previously described (238). This preparation allows neurons to be recorded without enzymatic dissociation, with the surrounding satellite glia cells and neighboring neurons intact (117, 118) but does not allow voltage clamp of sodium currents. DRG were continuously perfused with artificial cerebrospinal fluid (in mM: NaCl 130, KCl 3.5, NaH₂PO₄

1.25, NaHCO₃ 24, Dextrose 10, MgCl₂ 1.2, CaCl₂ 1.2, 16 HEPES, pH=7.3, bubbled with 95% O₂/ 5% CO₂). Cells were classified by conduction velocity (stimulation of attached dorsal root) as follows: <1.2 m/s, C; ≥7.5 m/s, A β ; between 1.2 and 7.5 m/s, A δ (240). Excitability parameters were analyzed as described previously in (15). Briefly, after measurement of any stable spontaneous activity, action potential parameters were measured during the smallest depolarizing current that could evoke an action potential (rheobase). Longer suprathreshold current steps were then applied to determine the maximum number of action potentials that could be evoked, and whether subthreshold membrane oscillations (with characteristic frequencies in the range of 100–200Hz) could be evoked.

Patch clamp recordings of sodium currents: Adult rat DRG ganglia were dissociated and grown in culture as previously described (19, 25). Transient, persistent, and resurgent sodium currents were recorded from neurons after 14–28 hours in primary culture. Neurons were dissociated from sham or inflamed (after 3 days) L4 and L5 DRGs or 3 days after siRNA injection and DRG inflammation. The extracellular solution consisted of (in mM): 130 NaCl, 30 TEA chloride, 1 MgCl₂, 3 KCl, 1 CaCl₂, 0.05 CdCl₂, 10 HEPES, and 10 Dextrose, pH 7.3. The pipette solution contained (in mM) 140 CsF, 10 NaCl, 1.1 EGTA, and 10 HEPES, pH 7.3. Resurgent currents were recorded using a two-voltage step protocol. A 20ms, +30mV voltage pulse was first used to inactivate transient sodium currents. This was followed by a series of repolarizing pulses to elicit

resurgent currents. The repolarizing pulses were 450ms long, from +5 to -85mV in 5mV steps. Resurgent currents were measured as the peak inward current elicited during the repolarizing step. Persistent currents were measured during the last 20ms of the 450ms repolarization pulses. Transient current amplitudes were measured using a steady-state inactivation protocol that depolarized the membrane to 0mV from 500ms pre-holding at voltage levels from -130 to -5mV, with an increment of 5mV. Peak transient currents were measured from the pre-holding level of -110 mV. Peak transient, resurgent and persistent currents were normalized to cell capacitance and expressed as current density. Voltage-dependence of inactivation and activation of the transient current was determined as in reference (19); values of $V_{1/2}$ (voltages at which activation or inactivation was half maximal) are reported. Cells used for recording had diameters of 35–45 μ m. The median capacitance was 53.8pF with 25th–75th percentile falling in the range 45–65pF.

Immunohistochemistry

DRG sections were cut at 40 μ m on a cryostat after fixation in 4% paraformaldehyde in 0.1M Phosphate Buffer and 4% sucrose. The primary Nav β 4 antibody was from Alomone (Jerusalem, Israel, catalog ASC-044) used at a dilution of 1:150. The secondary antibody conjugated to Alexa Fluor 594 (Invitrogen, Carlsbad, CA) was used at a dilution of 1:1000. Images from multiple sections of each DRG were captured under an Olympus BX61 fluorescent

microscope using Slidebook 4.1 imaging acquisition software (Intelligent Imaging Innovation, Denver, CO). To measure the expression of Nav β 4 in the DRG neurons, the summed intensities of the Nav β 4 signal were measured and normalized by the cellular area in each analyzed section to give an intensity ratio. In all immunohistochemical experiments, data from at least four animals were included to control for interanimal variability. For experiments examining the effect of Nav β 4 knockdown on Nav1.6 expression, the procedure was the same as described above except that the polyclonal antibody against Nav1.6 was used (Alomone; catalog ASC-009, used at 1:100 dilution). For quantification of immunohistochemical data, sections from different experimental groups were examined in a side-by-side protocol with identical display parameters.

Immunocytochemistry

To verify knockdown of Nav β 4 protein in dissociated DRG cultures under the conditions used for patch clamp measurements of sodium currents, L4/L5 ipsilateral LID DRG ganglia were harvested and cultured from rats injected with non-targeting control or Nav β 4-siRNA three days after siRNA injection and DRG inflammation. DRG neurons were fixed after 24 hours in culture with 4% paraformaldehyde (0.1M phosphate buffer, pH 7.4) for 20 minutes and washed in phosphate buffered saline (PBS) three times. Cells were permeabilized in 1% Triton X-100 in PBS for 20 minutes at room temperature (~22 °C), washed in PBS three times, blocked for 2 hours (10% normal goat serum, 0.1% Triton X-

100 in PBS) at room temperature and washed an additional three times in PBS. Cells were then incubated with primary antibody against Nav β 4 (#Ab80539, Abcam, Cambridge, MA, USA) diluted 1:500 in blocking solution at 4°C overnight. After three washes, cells were incubated with secondary antibody diluted in blocking solution 1:1000 (Alexa Fluor® 488 Goat Anti-Rabbit IgG, Molecular Probes, Life Technologies, Grand Island, NY, USA) for 2 hours at room temperature. Coverslips were mounted unto microscope slides with Prolong Gold Antifade (Molecular Probes). Cells were imaged with Nikon Eclipse TE2000-E microscope. Images were analyzed with NIS Elements Advance (Nikon®) software.

Western blot analysis of Nav β 4

DRGs were isolated and homogenized in ice-cold lysis buffer (50mM Tris pH 7.4, 5mM EDTA pH 8), 1% Triton X-100 and protease inhibitor cocktail (Complete, EDTA-free, Roche, Life Sciences, Indianapolis IN USA) followed by centrifugation at 57,000 x g at 4°C for 60 minutes. Samples (20 μ g of total protein per lane) were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) running in NuPAGE MES SDS running buffer (Invitrogen). Reducing conditions were used to break covalent bonds to the α subunits (198, 228). Electrophoresis was followed by electrophoretic transfer to nitrocellulose membrane (Bio-Rad, Hercules, CA, USA) in Tris-glycine-SDS transfer buffer. Nonspecific binding sites were blocked with 5% nonfat dry milk in

Tween (Bio-Rad; 0.1%)–phosphate-buffered saline at room temperature for 1 hour. The rabbit antibodies to Nav β 4 (1:400, Alomone) and to β -Actin (1:2000, Abcam) were applied to the blot followed by incubation with immunopure peroxidase conjugated goat anti-rabbit IgG (H+L) (1:20,000, Pierce, Rockford, IL). The signal was detected using a ChemiDoc-It system controlled by VisionWorksLS software version 7 (UVP, Upland, CA). After background subtraction, signals in the Nav β 4 band were normalized to the intensity of the β actin bands.

Data analysis

Behavioral time course data were analyzed using two-way repeated measures ANOVA with Bonferroni post-hoc test to determine on which days experimental groups differed. For electrophysiological, Western blot, and immunohistochemical data, comparison of values between different experimental groups was done using nonparametric methods for data that did not show a normal distribution based on the D'Agostino and Pearson omnibus normality test. The statistical test used in each case is indicated in the text, or figure legend. Significance was ascribed for $p < 0.05$. Levels of significance are indicated by the number of symbols, e.g., *, $p = 0.01$ to < 0.05 ; **, $p = 0.001$ to 0.01 ; ***, $p < 0.001$. Data are presented as the mean \pm S.E.M.

RESULTS

Nav β 4 knockdown reduces mechanical hypersensitivity in the DRG inflammation model

Previous studies have shown that local inflammation of the L5 DRG (LID) causes pronounced mechanical hypersensitivity in the ipsilateral hindpaw as measured by the von Frey test. LID also produces mechanical allodynia as measured by the withdrawal responses to stroking the paw with a light cotton wisp; and cold allodynia as measured by increased withdrawal to acetone stimuli (116, 238, 241). These behaviors are observed as early as postoperative day (POD)1. The mechanical hypersensitivity is maintained for at least 4 weeks at which point the other behaviors are beginning to resolve. In the present study, similar results were obtained when non-targeting (n.t.) control siRNA was injected into the L4 and L5 DRG just prior to DRG inflammation (Figure 15). In the control group, the von Frey threshold differed from baseline on all tested days. However, in animals injected with siRNA directed against Nav β 4, the ipsilateral mechanical hypersensitivity (von Frey test) was significantly reduced compared to control siRNA on all days tested, and differed from baseline only on POD1. The ipsilateral mechanical allodynia responses (cotton wisp test) were also significantly reduced from the control siRNA group on most days (Figure 15B), and were significantly different from baseline only on POD1. In contrast, cold allodynia (acetone test) induced by DRG inflammation was not significantly

reduced by Nav β 4-siRNA, either ipsilaterally (Figure 15C) or contralaterally. As previously reported in this model (14, 238), contralateral von Frey threshold reductions in the control siRNA group were very modest, with the lowest average value observed on any day being 11 grams. In the Nav β 4-siRNA group, contralateral thresholds differed from baseline only on POD1. No animals in either group showed contralateral responses to the mechanical allodynia test on any day (data not shown). As shown in Figure 15, Nav β 4-siRNA had no effect on baseline behaviors prior to implementation of the pain model; however, the tests used reached cut-off values and would not have detected increased thresholds.

Figure 15: Effects of Navβ4 knockdown on pain behaviors elicited by local inflammation of the L5 DRG. Baseline measurements plotted on post operative day (POD) 0 are the average of 2 measurements made 3-5 days prior to inflammation of the L5 DRG and injection of siRNA directed against Navβ4 or non-targeting control siRNA on POD0. The behavioral data was obtained from the ipsilateral paw of the animals. **A**, Mechanical threshold measured by the von Frey test was significantly reduced for the duration of the experiment in the n.t. injected animals. In Navβ4-siRNA injected animals the threshold differed from the n.t. animals on all days except baseline. **B**, Mechanical allodynia, measured as withdrawal to stroking the paw with a fine cotton wisp, was never observed prior to DRG inflammation (average baseline plotted on POD0), was increased by DRG inflammation in n.t. siRNA injected animals, and was significantly less on most days in Navβ4-siRNA injected animals. In Navβ4-siRNA injected animals the decreased threshold was significantly different from baseline only on POD1; in n.t. injected animals the decreased threshold differed significantly from baseline on all POD except POD 14 and 22. **C**, Cold allodynia, measured as withdrawal to a drop of acetone placed on the paw, was increased by DRG inflammation but not significantly affected by Navβ4-siRNA. N=6 n.t. and 8 Navβ4-siRNA injected male rats. *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$, significant difference between the two groups (two-way repeated measures ANOVA with Bonferroni posttest). Differences from baseline on later POD within each group discussed above were tested using one-way ANOVA with Dunnett's posttest. The data presented in the figure were not obtained with blinding of the experimenter; however, the findings about the initial time course of pain behaviors were confirmed in a separate experiment in which the experimenter was blinded to the siRNA status of the animals, $n=4$ per group, data not shown.

Immunohistochemistry and Western blotting confirm Nav β 4 knockdown by siRNA
and upregulation by DRG inflammation

Immunohistochemical staining for Nav β 4 was performed in DRG sections from normal animals, and on POD4 after DRG inflammation and injection of non-targeting or Nav β 4-siRNA. The immunohistochemical staining of Nav β 4 showed that DRG inflammation upregulated Nav β 4 and this upregulation was blocked by Nav β 4-siRNA (Figure 16A-D). This result was confirmed by Western blotting (Figure 16E). A representative Western blot is shown in Figure 16F. Nav β 4 protein signal (24kDa) was normalized to actin protein signal (42kDa). In a separate set of immunohistochemical experiments, examination of sections from both normal and inflamed DRGs showed that Nav β 4 was not as highly expressed in the cells with the smallest cross-sectional areas. The average cell area of Nav β 4-positive cells was larger than that of Nav β 4-negative cells in both conditions, and there were no striking changes in the cell size distribution after DRG inflammation. The inflammation-induced increase in staining for Nav β 4 seemed to be primarily due to an increase in the intensity per cell rather than an increase in the percentage of cells expressing Nav β 4; 62% of all cells scored in normal DRG were Nav β 4-positive ($61.5\% \pm 2.2\%$, based on average values from 4 animals), while 67% of all cells scored in inflamed DRG were Nav β 4-positive ($67.7\% \pm 3.4\%$, based on average values from 4 animals). This apparent increase in percentage was not significant when analyzed based on the average animal values ($p=0.17$, t-test) and could not account for the overall 64%

increased average intensity in inflamed compared to normal DRG shown in Figure 16D. Nav β 4 has also been observed in peripheral axons and nodes (228). The data in Figure 16A-D were obtained from cellular regions of the DRG sections, however, Nav β 4 was also observed in axonal regions, albeit at lower intensities. These regions also showed increased staining after DRG inflammation and reduced staining after Nav β 4-siRNA injection (data not shown).

Figure 16: Immunohistochemical and Western blot detection of Navβ4. Sample sections stained for Navβ4 are shown from normal DRG (**A**), and DRG 4 days after DRG inflammation (“LID”) and injection of either Navβ4 (β4 siRNA, **B**) or non-targeting (n.t.) siRNA (**C**). Scale bar, 50μm. **D**, summary data of Navβ4 intensity normalized to cellular area in DRG sections. **, p<0.01; ***, p<0.001 significant difference between the indicated groups (one-way ANOVA with Tukey’s posttest). n=4 animals per group, 19 to 34 sections per animal. Graph and statistical analysis are based on the animal averages. **E**, Summary data of the ratio of Navβ4 intensity to actin intensity from Western blot analysis of the same 3 experimental groups. Actin always appeared as a double band and both lanes were included in the actin measurement. *, p<0.05; **, p<0.01; significant difference between the indicated groups, one-way ANOVA with Tukey’s posttest. n=6 samples per group. **F**, Two sample lanes from each experimental group. Some intervening lanes from a different experiment run on the same gel have been removed. Male and female animals were used for these experiments.

Nav β 4 knockdown reduces Nav1.6 expression

The Nav β subunits can also regulate localization and trafficking of the α subunits. We therefore examined the effect of Nav β 4-siRNA on expression of Nav1.6 in DRG sections. DRG were inflamed and injected with siRNA directed against Nav β 4 or the non-targeting (n.t.) control construct. Four days later DRGs were fixed and sectioned and stained for Nav1.6. As shown in the examples in Figure 17, the expression of Nav1.6 was higher in n.t. siRNA injected DRG (Figure 17A-C) than in Nav β 4-siRNA injected DRG (Figure 17D-F). Summary data from 4 animals per group, 104 sections per animal, showed that Nav1.6 was 1.6 ± 0.18 times higher in n.t. siRNA injected DRG than in Nav β 4-siRNA injected DRG (ratio t-test based on animal averages, $p=0.002$).

Figure 17: Effect of Nav β 4-siRNA on immunohistochemical detection of Nav1.6 in DRG sections. Sample sections are shown from DRG 4 days after DRG inflammation and injection of either non-targeting siRNA (**A**, **B**, **C**) or Nav β 4-siRNA (**D**, **E**, **F**). Scale bar, 100 μ m.

Navβ4 knockdown reduces hyperexcitability induced by
DRG inflammation in Aβ sensory neurons.

It had been previously shown by our colleagues that DRG inflammation leads to marked neuronal hyperexcitability and spontaneous activity of myelinated Aβ neurons in the inflamed DRG, as measured on POD 3-4 in the isolated whole DRG preparation with sharp electrode recording Methods (238). In addition, it was also shown that injecting siRNA directed against Nav1.6 restored many of these hyperexcitability parameters towards normal values(14). In our collaboration, we observed a similar reduction of inflammation-induced hyperexcitability of Aβ myelinated cells by injecting Navβ4-siRNA at the time of DRG inflammation (Figure 18). Spontaneous activity induced by DRG inflammation was restored to normal levels by the Navβ4-siRNA. The LID-induced decrease in rheobase was partially normalized by the Navβ4-siRNA (Figure 18B); a similar result was observed when spontaneously active cells, with rheobase defined as zero, were excluded from the calculation (data not shown). The observed changes in rheobase did not reflect changes in input resistance ($16.3 \pm 0.1 \text{ M}\Omega$, $16.0 \pm 0.7 \text{ M}\Omega$, and $17.0 \pm 0.7 \text{ M}\Omega$ in normal + n.t. siRNA, LID + Navβ4-siRNA, and LID + n.t. siRNA, respectively; no significant differences between groups per Kruskal-Wallis test with Dunn's post-test). DRG inflammation caused a small depolarization of the resting membrane potential (from $-66.2 \pm 0.5 \text{ mV}$ to $-62.1 \pm 0.7 \text{ mV}$) that was partially normalized by Navβ4-siRNA (to $-64.1 \pm 0.5 \text{ mV}$; Figure 18D). Action potential duration was slightly increased by LID but

not affected by Nav β 4-siRNA (Figure 18C). Action potential threshold did not differ between the three groups. Parameters particularly associated with resurgent and persistent currents, such as the ability to fire repetitively or show subthreshold membrane oscillations in response to long suprathreshold current injections, were also increased by DRG inflammation and largely normalized by Nav β 4 knockdown (Figure 18E-F). The number of A δ cells observed in these experiments was relatively small (26 in the control group, only 8 in the LID + non-targeting siRNA group, and 45 in the LID + Nav β 4-siRNA group); few significant differences in the electrophysiological parameters were observed and none of the A δ cells showed spontaneous activity (data not shown). In contrast, excitability parameters of C cells were much less affected by DRG inflammation or Nav β 4-siRNA. Spontaneous activity was low or zero in DRG neurons treated with Nav β 4-siRNA or non-targeting siRNA and there were no significant differences between the groups. Rheobase, membrane potential, and the ability to fire repetitively were not affected by DRG inflammation or by Nav β 4-siRNA (data shown in (242)).

Figure 18: Navβ4 knockdown reduces hyperexcitability of myelinated Aβ cells induced by DRG inflammation. L4/L5 DRGs were injected in vivo with either Navβ4 or non-targeting siRNA and inflamed ("LID"). For comparison normal DRGs were injected with non-targeting siRNA but not inflamed. Four days later DRGs were isolated for in vitro whole DRG microelectrode recording. Data are from myelinated Aβ cells based on dorsal root conduction velocity. **A**, Incidence of spontaneous activity was increased by LID and normalized by Navβ4 knockdown. **B**, Rheobase was reduced by LID and partially normalized by Navβ4 knockdown. **C**, Action potential duration was modestly increased by LID but not affected by Navβ4-siRNA. **D**, Resting membrane potential was depolarized by LID and partially normalized by Navβ4-siRNA. Responses to longer suprathreshold current injections showed that the percentage of cells that could be induced to fire repetitively (> 2 action potentials; **E**) or demonstrate subthreshold oscillations (**F**) was significantly increased by LID and partially normalized by Navβ4-siRNA. *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$; significant difference between groups, χ^2 test (**A**, **E**, **F**); Kruskal-Wallis test with Dunn's multiple comparison posttest (**B**, **C**); ANOVA with Bonferroni's posttest (**D**). $n = 123$ normal + n.t. siRNA cells from 4 female rats, $n = 74$ LID + n.t. siRNA cells from 3 female rats, and $n = 172$ LID + Navβ4-siRNA cells from 6 female rats.

DRG inflammation increases transient and resurgent TTXS
sodium currents in medium diameter cells in vitro.

We next examined the effects of DRG inflammation and Nav β 4 knockdown on resurgent sodium currents, since these currents are thought to facilitate high frequency repetitive firing. Transient, resurgent, and persistent sodium currents were recorded in acutely isolated, medium to large diameter (35 to 45 μ m) neurons from DRGs from sham operated animals or DRGs isolated 3 days after DRG inflammation. Medium to large sized DRG neurons with 35 to 45 μ m diameter were chosen to ensure a better quality of recording and better voltage control. DRG neurons with a diameter greater than 45 μ m were not examined. In addition, previous microelectrode studies have shown that spontaneous activity occurs primarily in A β cells towards the smaller end of the diameter distribution (238). Previous patch clamp studies showed that medium to large diameter neurons have a high likelihood of expressing Nav1.6, the main carrier of TTXS resurgent current in DRG neurons (27). Cells were classified as having predominantly TTXS current (based on fast current kinetics and a single component in their steady-state inactivation curves) or mixed TTXS and TTXR currents, as previously described (88, 243). Because previous studies with this model showed that spontaneous activity and hyperexcitability are predominantly observed in A β cells and are TTXS (238), we focused on the subset of cells that predominantly express TTXS currents. In addition, cells with predominantly TTXS current have previously been observed to be the ones to express TTXS

resurgent currents (25). Excluding cells with mixed TTXR and TTXS sodium currents also most likely excluded most cells with $A\bar{\delta}$ conduction velocities as measured in vivo (84), even though those would otherwise be expected to be enriched in the size range examined. In those cells with predominantly TTXS current, both peak transient and peak resurgent current densities were increased by DRG inflammation (Figure 19). The ratio of resurgent to transient current increased from 0.034 ± 0.002 in control cells to 0.041 ± 0.002 in inflamed cells ($p=0.02$, Mann-Whitney test). The persistent current density was $4.0 \pm 0.63\text{pA/pF}$ in control cells vs. $5.7 \pm 0.61\text{pA/pF}$ in cells from inflamed DRG ($p=0.055$, Mann-Whitney test). The ratio of persistent to transient current was 0.003 ± 0.0005 in control cells and 0.003 ± 0.0004 in cells from inflamed DRG ($p=0.46$, t- test).

Cells from inflamed DRG also had a negative shift in the voltage-dependence of activation of the transient current ($V_{1/2}$ of $-46.4 \pm 0.9\text{mV}$ compared to $-41.8 \pm 1.6\text{mV}$ in control cells; $p=0.03$, t-test). There was also a small shift in steady-state inactivation ($\sim 2.5\text{mV}$) which may not have had a major impact on channel availability ($V_{1/2}=-57.3 \pm 0.8\text{mV}$ in LID cells vs. $-59.9 \pm 0.8\text{mV}$ in control cells, $p=0.04$, t test).

Figure 19: TTXS resurgent and transient currents are increased by DRG inflammation.

Sodium currents were recorded in acutely cultured medium to large diameter DRG neurons from sham operated animals (control) or animals with localized inflammation of the DRG (LID) at POD3. Data are from medium to large diameter cells that expressed only TTXS sodium current. Representative traces of resurgent current recordings are shown for control (A) and LID (B) cultured DRG neurons. The much larger transient current during the 20 mV pre-pulse (inset: voltage protocol) is off-scale. C-E, Summary data shows both peak transient current (C) and resurgent current (E) densities were higher in cells from inflamed DRG (n=15 cells from 3 male rats) compared to sham control DRG (n=20 cells from 3 male rats). Increase in persistent current (D) did not reach significance (p=0.055, Mann-Whitney test). **, p<0.01; ***, p<0.001; significantly different from sham control (C, t-test; E, Mann-Whitney test).

Navβ4 knockdown in vivo preferentially reduces TTXS persistent and resurgent currents in medium to large diameter neurons cultured from inflamed DRG

In a separate set of experiments, transient, resurgent, and persistent sodium currents were recorded in acutely isolated, medium to large (35 to 45μm) diameter neurons from cultured DRGs isolated 3 days after in vivo DRG inflammation and injection of either non-targeting control or Navβ4-siRNA. Cells having only TTXS currents were chosen to study based on the same criteria and reasons described above. In those cells, densities of both resurgent currents and persistent currents were reduced by the Navβ4-siRNA (Figure 20). The ratio of resurgent to transient current was also significantly lower in Navβ4-siRNA treated cells (0.048 ± 0.003 with n.t. siRNA vs. 0.033 ± 0.002 with Navβ4-siRNA, $p=0.0003$, Mann-Whitney test). In addition, the ratio of persistent to transient current was lower (0.0034 ± 0.0003 in n.t. siRNA group vs. 0.0023 ± 0.0003 , $p=0.0005$, Mann-Whitney test). Navβ4 knockdown also resulted in a depolarizing shift in the voltage-dependence of activation of the transient current (from $V_{1/2}$ of -48.2 ± 1.9 to -42.4 ± 1.2 mV, $p=0.01$, t-test). There was no significant difference between the 2 groups in the voltage-dependence of inactivation.

Knockdown of Navβ4 under the experimental conditions used for the patch clamp recordings was confirmed with immunostaining of cultured neurons (Figure 21). To parallel the protocol used for the patch clamp experiments, siRNA (non-targeting or Navβ4 directed) was injected in vivo at the time of DRG

inflammation; DRGs were isolated and dissociated 3 days later, and cultured cells were fixed and stained after 24 hours in culture.

Figure 20: Navβ4 knockdown in vivo reduces TTXS persistent and resurgent currents in medium to large diameter neurons cultured from inflamed DRG. Sodium currents were recorded in acutely cultured medium to large diameter DRG neurons from LID animals injected with non-targeting (n.t.) or Navβ4-siRNA. Data are from neurons that expressed only TTX-sensitive current. Representative traces of resurgent current recordings are shown for LID +n.t. siRNA (**A**) and LID + Navβ4-siRNA (**B**) groups. The much larger transient current during the 20 mV pre-pulse (inset: voltage protocol) is off-scale. **C-E**: Summary data shows both persistent current (**D**) and resurgent current (**E**) densities were reduced in LID + Navβ4-siRNA (n=31 from 5 males rats) group relative to LID + n.t.siRNA (n=25 from 5 males rats). No difference was observed in transient current density. **, p<0.01, ***, p<0.001, significantly different from n.t. siRNA group (**D**, Mann-Whitney test; **E**, t-test).

Figure 21: Immunocytochemical detection of Navβ4 in cultured DRG cells. DRG neurons were obtained under the same conditions as for the electrophysiological experiments in Figure 20. L4/L5 DRG were isolated at POD3 and cultured for 24 hours before fixation and staining. Representative images of DRG neurons cultured from LID animals injected with n.t. siRNA (**A**) or Navβ4-siRNA (**B**). Scale bars are 50 μ m. **C**, Summary data of intensity per cell area shows decreased Navβ4 staining for LID + Navβ4 (n=1164 from 4 male rats) cultured DRG neurons relative to LID + n.t siRNA (n=1132 from 3 male rats). ***, significant difference between the groups ($p < 0.001$), t test. Intensity units are not comparable to Figure 16D because different microscopes and analysis programs were used.

Discussion

In this collaborative study we investigated the effects of Nav β 4 knockdown on pain associated behaviors, DRG neuronal excitability and sodium currents. Knockdown of Nav β 4 via intraganglionic siRNA injection prevented the development of persistent mechanical hypersensitivity after local inflammation of the DRG and reduced inflammation induced increases in neuronal excitability. Nav β 4 expression was upregulated on POD 3-4 in DRG neurons from LID animals. At this time point, POD 3-4, DRG inflammation increased TTXS resurgent and transient currents in medium to large diameter neurons. Nav β 4 knockdown selectively reduced the inflammation induced increase of resurgent currents and persistent currents but did not alter transient current density.

β -subunits can be expressed in nonneuronal cells and have effects independent of the Nav α subunits (136, 244). However, our immunohistochemical data in DRG sections and cultured neurons show that the majority of DRG neurons express Nav β 4. The behavioral effects of Nav β 4 knockdown in the lumbar DRG are also strikingly similar to those of Nav1.6 knockdown (14). The only difference between Nav β 4 and Nav1.6 knockdown was at POD1. At this time point, Nav β 4 knockdown effect on von Frey responding was only partially reversed but the Nav1.6 knockdown effect is a complete reversal to baseline level. Both Nav β 4 and Nav1.6 knockdown reduce mechanical pain behaviors for the duration of the experiment (at least 4 weeks).

As it is unlikely that the single siRNA injection was effective for this long, we interpret this to mean that an early period of spontaneous activity is required to initiate long lasting pain behaviors, consistent with other studies in this and other rat pain models (15, 119, 238).

We propose two mechanisms that may contribute to the observed behavioral and electrophysiological effects of Nav β 4 knockdown and reduction of spontaneous activity in myelinated A β cells: (1) reduction of Nav1.6 expression; and (2) reduction of resurgent and persistent current, mitigating their upregulation by DRG inflammation. The first potential mechanism reflects that, in addition to their roles regulating electrophysiological properties of the pore-forming α subunits, Nav β subunits have been shown to regulate trafficking to the membrane, subcellular localization, and even gene expression of α subunits (136, 228, 244). In the PNS, Nav β 4 is enriched at the nodes of Ranvier, particularly at nodes in large diameter axons. In the CNS, Nav β 4 may be localized at the axon initial segment, unmyelinated axons or at the nodes of Ranvier depending on the cell type and region (228). Nav β 4 co-expression did not increase peak Nav1.6 current in a heterologous expression system (227) though not all aspects of sodium channel function are captured in such systems. While we did detect a reduction in Nav1.6 immunohistochemistry with Nav β 4 knockdown relative to control siRNA, we did not see a reduction in TTXS current density in corresponding patch clamp experiments, which were conducted on a defined subset of neurons. In our previous study with large diameter neurons in

the higher end of the cell size spectrum (~60 μm ; see Part I), we did detect a small reduction in TTXS current density with Nav β 4 knockdown. The β subunit background may be different between these two populations (35-45 μm vs. 60 μm). Therefore, by knocking down Nav β 4 other beta subunits may compensate depending on the cell background. It is also possible that not all the Nav1.6 protein visualized by immunohistochemistry was necessarily functional membrane-localized channels; conversely the patch clamp experiments may not reflect changes in axonal current densities. The staining for Nav1.6 was diffuse and did not appear restricted to the membrane. However, we did not use thin sections to specifically address this question but other studies have shown a similar pattern (13, 222, 245). Details of possible Nav β 4 effects on α subunit trafficking and expression require further study. In particular, studies with other β subunits suggest two potential pathways that may regulate trafficking and expression (244). Nav β s are part of the immunoglobulin CAM superfamily and the extracellular domain is essential for CAM activity (198, 246). Therefore, one way Nav β s may regulate VGSC localization is through interactions with the extracellular matrix or other CAMs. On the other hand, Nav β subunits have been reported to interact with cytoskeletal proteins such as Ankyrin which may regulate expression and localization of VGSCs (228, 247, 248).

The second proposed mechanism to explain the impact of Nav β 4 knockdown focuses on alterations in sodium channel gating properties. The electrophysiological parameters that seem to best correlate with mechanical

hypersensitivity is the incidence of high-frequency spontaneous activity in A β neurons. Increased resurgent and persistent currents can facilitate such high frequency spontaneous activity, and Nav β 4 knockdown effects on these currents may have contributed to our electrophysiological and behavioral findings. The decrease in resurgent and persistent currents in voltage clamp experiments in response to Nav β 4-siRNA was not due to a decrease in total TTXS current (which was unaffected by the siRNA); both the absolute values and the ratios of resurgent-to-transient and persistent-to-transient current were significantly reduced by Nav β 4 knockdown. Nav β 4 knockdown also decreased persistent sodium currents in cerebellar granule neurons (197). Consistent with known properties of persistent currents, we observed that DRG inflammation depolarized the resting membrane potential of A β neurons, an effect that was partially reversed by Nav β 4 knockdown. Although other sodium channel α subunit isoforms can generate resurgent currents when the cytoplasmic terminal peptide of Nav β 4 is introduced, in vivo, fast TTXS resurgent currents in most (though not all) of the neurons studied to date seem likely to be the result of Nav β 4 in association with Nav1.6, in both central and DRG neurons (27, 182, 228, 249). The upregulation of Nav β 4 in the DRG inflammation model is a plausible mechanism for facilitating the high frequency repetitive firing seen in spontaneously active A β neurons. In our experimental conditions knockdown of either Nav β 4 or Nav1.6 had relatively minor effects on evoked single action potentials, and no effect on action potential duration, but pronounced effects on spontaneous activity or repetitive firing capability. Our results suggest that the

latter two electrophysiological parameters best correlate with mechanical hypersensitivity.

Changes in the voltage-dependence of sodium channel activation and inactivation can also contribute to altered excitability. Previous studies examining the impact of Nav β 4 on recombinant Nav1.6 channels expressed in heterologous cells such as HEK293 cells indicate that Nav β 4 can induce negative shifts in the voltage-dependence of activation (by almost -10 mV) and, to a lesser extent, steady-state inactivation (227). We observed a hyperpolarizing shift in activation with inflammation of the DRG; this is likely to enhance spontaneous firing in sensory neurons. Nav β 4 knockdown also induced a +6 mV shift in the voltage-dependence of activation, supporting the notion that Nav β 4 subunits modify Nav1.6 voltage-dependence of activation. In our previous study (see Part I), co-expression of rat Nav β 4 with human Nav1.6 did not produce a change in activation in small diameter neurons (203). A possible explanation for this discrepancy is that inflammation may trigger additional mechanisms (e.g., activating kinase pathways) that endow Nav β 4 to mediate this enhanced activity. The effect may depend on neuronal background (e.g., small diameter vs. medium diameter neurons). An alternative possibility is that the small species differences between human Nav1.6 and rat Nav1.6 account for this effect. Interestingly, co-expression of Nav β 4 with mouse Nav1.6 which is more similar to rat Nav1.6 than human, did produce a similar shift in activation (data not shown).

Our results with the LID model confirm work in the previous section showing that Nav β 4 is primarily expressed in larger sensory neurons and extend it by showing that it plays a key role in mediating resurgent currents in inflamed, hypersensitive sensory neurons (23, 198, 203). In this study, the patch clamp experiments on sodium currents were conducted on medium diameter neurons expressing only TTXS sodium currents. This focus was dictated by our collaborators' previous work showing that spontaneous activity in this model is sensitive to TTX and largely observed in cells at the smaller end of the size range for A β neurons(238). By excluding cells expressing both TTXR and TTXS currents, we most likely eliminated many A δ neurons (84). TTXR resurgent sodium currents mediated by Nav1.8 and enhanced by the Nav β 4 cytoplasmic terminus have also been observed in DRG neurons (25). These resurgent currents activate over an order of magnitude more slowly than those mediated by Nav1.6; e.g. at -20mV the times to peak are 130ms for TTXR resurgent current currents compared to 3.5ms for TTXS resurgent currents. Thus, it is not clear if these TTXR currents could facilitate the high frequency firing observed in the LID model, in which the interspike interval is commonly less than 10ms. Nav1.8 has recently been found to be upregulated in myelinated A β neurons by peripheral inflammation (CFA paw injection) (250) and therefore a possible role of Nav1.8 in our model remains to be investigated. Arguing against Nav1.8 playing a predominant role in our model are the observations that peripheral inflammation with CFA and local DRG inflammation yield DRG gene expression changes with almost no overlap (251), and the reduction of pain associated behaviors and

spontaneous activity by Nav1.6 knockdown in the LID model (14). In addition, preliminary experiments from our collaborators in the Zhang lab using protocols similar to the current study showed no effect of Nav1.8 knockdown on pain associated behaviors induced by DRG inflammation through POD 4.

In conclusion, although Nav1.6 has not generally been considered a good therapeutic target for pain, due to its widespread distribution and key role in the node of Ranvier, our results suggest that targeting the persistent and resurgent currents generated by this channel (which appear to depend on Nav β 4) might be a promising approach.

PART III: FHF2 ISOFORMS DIFFERENTIALLY REGULATE Nav1.6-MEDIATED RESURGENT SODIUM CURRENTS IN DORSAL ROOT GANGLION NEURONS.

Summary

The sodium channel subtype Nav1.6 as well as the Nav1.6-mediated resurgent currents have been implicated in several pain pathologies. However, our knowledge of how fast resurgent currents are modulated in DRG neurons is limited. This study explored the potential regulation of Nav1.6-mediated resurgent currents by isoforms of Fibroblast growth Factor Homologous factor 2 (FHF2) in an effort to address the gap in our knowledge of resurgent current modulation. FHF2 isoforms colocalize with Nav1.6 in peripheral sensory neurons. Heterologous expression of FHF2 isoforms suggests that these proteins differentially regulate inactivation of VGSCs. In particular, FHF2A mediates long-term inactivation (175), a mechanism proposed to compete with the open channel blocker mechanism that mediates resurgent currents. On the other hand, FHF2B lacks the ability to mediate long-term inactivation and may delay inactivation, favoring open channel block. Based on these observations, we hypothesized that FHF2A limits the generation of resurgent current, whereas, FHF2B enhances resurgent currents. Overall, our results suggest that FHF2A negatively regulated fast resurgent current by enhancing long-term inactivation and delaying recovery. In contrast, FHF2B positively regulated resurgent current

and did not alter long-term inactivation. Chimeric constructs of FHF2A and Nav β 4 (likely the main open channel blocker in DRG neurons; see Part I) exhibited differential effects on resurgent currents suggesting that specific regions within FHF2A and Nav β 4 have opposing regulatory functions. Interestingly, FHFAs and FHF2B isoforms were differentially regulated in a radicular pain model in a manner that likely contributes to enhanced resurgent currents. As such, these findings suggest that FHF2A and FHF2B regulate resurgent current in DRG neurons and may contribute to hyperexcitability associated with some pain pathologies.

Materials and Methods

cDNA constructs

These studies used cDNA constructs of the sodium channel auxiliary subunits, FHF2A, FHF2B and chimeric constructs of FHF2A and Nav β 4. All constructs were tagged at the C-terminus with photostable monomeric Turquoise2 (pmTurquoise2) to verify expression. To generate the FHF2A and FHF2B tagged constructs, the coding sequence corresponding to mouse FHF2A (National Center for Biotechnology Information database (252) reference number: NP_034330.2) and human FHF2B (NP_378668.1) were synthesized and purchased from Genscript (Piscataway, NJ). Mouse FHF2A protein is 99.56% identical to human FHF2A (NP_004105.1) and is predicted to be 100%

identical to rat FHF2A (NC_005120.4). Human FHF2B protein is 99.48% identical to mouse (NP_001277344.1) and rat FHF2B (NP_445880.1). The FHF2A sequence was cut from a pUC57 vector and inserted into the pmTurquoise2-N1 vector with HindIII/KpnI restriction enzymes. The FHF2B sequence was cut from pcDNA3.1 (+) vector and inserted into pmTurquoise2-N1 vector with HindIII/BamHI restriction enzymes. The sequences were moved in-frame by site directed mutagenesis (Quickchange XL II Site Directed Mutagenesis kit, Agilent Technologies).

The chimeric constructs of FHF2A and Nav β 4 were designed by replacing the long-term inactivation particle sequence (AAAIASSLIRQKRQAREREK, 20 amino acids (175)) with the Nav β 4 open channel blocker sequence (KKLITFILKKTREKKKECLV, 20 amino acids (199)) to generate the F2A(β 4) construct. Conversely, the open channel blocker sequence in rat Nav β 4 (NP_001008880.1) was replaced with the long-term inactivation particle of FHF2A to generate the (β 4)F2A construct. The full chimeric sequences were synthesized and purchased from Genscript (Piscataway, NJ). The F2A(β 4) and (β 4)F2A sequences were cut from the pUC57 vector and sub-cloned into pmTurquoise-N1 with NheI/XhoI restriction enzymes. To move the sequences in frame with the fluorescent protein, the stop codon was mutated to a glycine residue using site-directed mutagenesis.

To study Nav1.6 in isolation from endogenous TTXS channels we used a

Nav1.6 TTXR construct previously described in (181). Briefly, the sequence corresponding to human Nav1.6 protein (NP_055006.1) was codon-optimized and purchased from Genscript (Piscataway, NJ). The sequence was then sub-cloned into pcDNA3.1 (+) with KpnI/XbaI restriction enzymes. The Nav1.6 sequence was then modified with site directed mutagenesis to confer high resistance to TTX by converting tyrosine residue 371 to serine as previously described (212, 213). The resulting construct was named Nav1.6r. Additionally, we knocked down endogenous TTXR Nav1.8 channels with a small hairpin RNA (shRNA) plasmid to aid in the isolation of Nav1.6r currents. The Nav1.8 shRNA-IRES-dsRED plasmid encoded for Nav1.8 shRNA sequence (targeting sequence, GATGAGGTCGCTGCTAAG, (214) and an internal ribosome entry site for the translation of fluorescent protein marker dsRed (IRES-dsRED) as previously described (19, 203).

Cell culture

DRG neurons were obtained from adult male Sprague Dawley rats. Rats were euthanized by CO₂ exposure and secondary decapitation. The spinal column was then removed and DRG were harvested from the lumbar to cervical region. The nerve processes were cut from the excised ganglia. Ganglia were then digested in Dulbecco' modified Eagle's Medium (DMEM, Fisher Scientific) containing collagenase (1.25 mg/mL) and neutral protease (0.78mg/mL) for 45 minutes at 37°C. Subsequently, the digested ganglia were centrifuged at

1000rpm for five minutes. Digestion media was aspirated and replaced with 10% Fetal Bovine Serum (FBS, Hyclone) DMEM (Invitrogen) and ganglia were mechanically dissociated with sequentially smaller glass pipettes. Dissociated ganglia were spun again at 700 rpm for five minutes. Media was aspirated and replaced with fresh 10% FBS DMEM media. Aliquots of cell suspension (~100 μ L) were loaded onto glass coverslips coated with poly-D-lysine and laminin. After 10 minutes, cells settled and 500 μ L of 10% FBS DMEM was added to each well. For electrophysiological experiments with transfected neurons, the 10% FBS DMEM media was supplemented with mitotic inhibitors, 5-fluoro-2-deoxyuridine (50 μ M, Sigma Aldrich) and uridine (150 μ M, Sigma Aldrich), to prevent overgrowth of the supporting cells. Cells obtained from dissociated DRG (neurons and supporting cells) grown in culture were maintained at 37°C in a humidified 95% air and 5% CO₂ incubator. Media was changed every two days.

For Localized Inflammation of the DRG (LID) experiments, the ipsilateral L4 and L5 DRG were excised from sham operated rats and inflammation-induced rats at post operative day 5. The above dissociation protocol and culture was followed with the exception of the digestion time, which was decreased to 28 minutes. Indiana University School of Medicine Institutional Animal Care and Use Committee approved the animal protocols described above.

Surgical procedure for localized inflammation of the DRG

Localized inflammation of the DRG was used as a model of radicular pain as previously discussed in (253) and described in (238). Adult male Sprague Dawley rats under isoflurane anesthesia were used for these procedures. After deep anesthesia was verified, an initial incision on the back near the spinal column was made from L3-S1 to expose and visualize the superficial area of the spine. Then, a second deeper incision was made on one side of the animal approximately 1mm from the center of the spine from L4 to S1. Paraspinal muscles near L4/L5 were carefully teased apart until the intervertebral foramen could be visualized using the transverse processes, ilium and dorsal/ventral ramus as guides. Aliquots of 10uL containing zymosan diluted in incomplete Freud's Adjuvant (2mg/mL) were injected near L4 and L5 DRG each, through a needle inserted close to the DRG through the intervertebral foramen. The needle was bent in a 90 degree angle ~2 mm from the tip for easier access and was left for two minutes after injection to prevent leakage. Sham operated animals were used as a control; the above procedure was followed with the exception of zymosan injection. Indiana University School of Medicine Institutional Animal Care and Use Committee approved the surgical procedure described.

Immunocytochemistry

To study the expression pattern of FHF2A and FHF2B after inflammation, the L4 and L5 ipsilateral DRG ganglia were harvested and dissociated from sham operated and inflammation induced animals at post operative day 5. DRG neurons were fixed after 24 hours in culture, permeabilized, blocked and treated with antibodies in the following manner: Cells were fixed with 4% paraformaldehyde (0.1M phosphate buffer, pH 7.4) for 20 minutes at room temperature, washed with phosphate buffered saline (PBS), permeabilized in 1% Triton X-100 in PBS for 20 minutes at room temperature, washed with PBS, blocked for 2 hours (10% normal goat serum, 0.1% Triton X-100 in PBS) at room temperature, washed with PBS, incubated in primary antibodies diluted in blocking solution overnight at 4°C, washed with PBS and incubated with secondary antibody in blocking solution for 2 hours at room temperature. Primary antibodies used were Anti-Pan-FHF-A (1:200, Clone N235/22, UC Davis/NIH NeuroMab Facility) and monoclonal Anti-FGF13/FHF2.B (1:200, Clone N225A/10, UC Davis/NIH NeuroMab Facility). Secondary antibody used was Alexa Fluor® 488 Goat Anti-Mouse IgG (Molecular Probes, Life Technologies) at 1:750 dilution. Coverslips were mounted on microscope slides with Prolong Gold Antifade (Molecular Probes). DRG neurons were imaged using an Axio Observer Z1 Widefield Microscope with a 20X objective (ZEISS Microscopy). Images were analyzed using NIS Elements Advance Research (Nikon®) software by defining each cell as a region of interest and quantifying the mean intensity signal for

FHF2A and FHF2B. The mean intensity signal was compared between sham and LID groups using Student's t-test. Quantification experiments were carried out independently at least five times; more than 1000 cells were counted for each condition.

Recombinant expression in DRG neurons

DRG neurons were transiently co-transfected with Nav1.6r, tagged auxiliary subunit and Nav1.8 shRNA-IRES-dsRED using the Helios Gene Gun (Bio-Rad Laboratories) 36-48 hours after dissociation in 2:1:1 ratio respectively. As a negative control, pmTurquoise 2 (tag only) was co-transfected instead of the auxiliary subunits. For peptide studies, only Nav1.6r and Nav1.8 shRNA-IRES-dsRED were co-transfected. Expression of the Nav1.6r construct with Nav1.8 shRNA allowed us to study the modulation of Nav1.6r by auxiliary subunits in isolation from endogenous channels as previously described (19, 203). Although endogenous TTXR Nav1.8 channels run down in culture (19, 216), by using the Nav1.8 shRNA-IRES-dsRED plasmid we further decreased Nav1.8 to minimize contamination. TTXR Nav1.9 currents are not observed under our recoding parameters as previously reported (217, 218). Endogenous TTXS channels were blocked with 500nM TTX.

Electrophysiology and data analysis

General Setup: Whole cell patch clamp recordings were obtained with a HEKA EPC-10USB amplifier. Data were acquired on a Windows-based Intel 2 Core computer using the Patchmaster program (version 2X65; HEKA Elektronik). Fire polished glass electrodes (0.7-1.1M Ω) were fabricated using a P-97 puller (Sutter), and tips were coated with dental wax to minimize capacitive artifacts and enhance series resistance compensation. The offset potential was zeroed prior to seal formation. Capacitive transients were canceled using computer-controlled circuitry; C-fast for pipette capacitance correction and C-slow for cell capacitance compensation. Voltage errors were minimized by series resistance compensation >75%. Membrane currents were sampled at 20KHz and filtered online at 10KHz. Leak currents were linearly cancelled by P/-5 subtraction (pulse/number). Whole cell patch clamp recordings in voltage clamp mode were obtained 2-3.5 days after transfection at room temperature (~22°C). Cells examined were selected based on fluorescence of Turquoise (corresponding to auxiliary subunit) and dsRed (corresponding to Nav1.8 shRNA) signal. For peptide studies, only the dsRed signal was used as selection criteria since no auxiliary subunits were co-transfected. Cells with residual Nav1.8 current greater than 3% of the peak current of Nav1.6r were excluded. Nav1.8 contamination was determined by examining the voltage-dependence of steady-state fast inactivation as described previously (203). Whole cell patch clamp recordings were started five minutes after the whole cell configuration was obtained.

Electrophysiology data were analyzed using the software programs Origin (version 8, OriginLab), Fitmaster (v2X65, HEKA Elektronik), Excel (Microsoft) and final graphs were made in Prism (version 6, GraphPad).

Recording solutions: The electrode solution consisted of 140mM CsF, 10mM NaCl, 1.1mM EGTA, and 10mM HEPES (adjusted to pH 7.3 with CsOH). The extracellular bathing solution contained 130mM NaCl, 30mM TEA chloride, 1mM MgCl₂, 3mM KCl, 1mM CaCl₂, 0.05mM CdCl₂, 10mM HEPES, 10mM D-glucose and 500nM TTX (adjusted pH 7.3 with NaOH). Recording solutions were adjusted using D-glucose to maintain physiological values of osmolarity (310 mOsm for internal solution and 320 mOsm for external solution).

Peptide Experiments: To study the effects of FHF2A's long-term inactivation particle, we used a FHF2A derived peptide corresponding to amino acids residues 2-21 as reported in (175). The peptide, FHFA, was modified with an N-terminal acetyl group and C-terminal hydroxyl group yielding the following sequence: Ac-AAAIASSLIRQKRQAREREK-OH (purchased from Biopeptides Co). The FHFA peptide was added to the electrode solution at a 1mM concentration. In the control group no peptide was added to the intracellular solution.

Steady-State Activation: Current-voltage (I/V) relationships were determined by steps of 50ms, from -100 to + 80mV, in 5mV increments. The

voltage-dependence of activation (m_{∞}) was determined from sodium currents elicited with I/V protocol from voltages of -100mV to 0mV. Conductance (G) values were calculated at each test potential (V_m) using the following equation, $G = \frac{I}{(V_m - V_r)}$. V_r is the voltage at which the direction sodium influx reverses. The reversal potential was quantified for each neuron Goldman-Hodgkin-Katz equation (221). Data were then normalized to the peak conductance, plotted as a function of voltage and fitted using single-phase Boltzmann distribution equation, $\frac{G}{G_{max}} = \left(\frac{1}{1 + e^{(V_m - V_{1/2})/k}} \right)$. The half-activating voltage ($V_{1/2}$) and slope factor (k) were obtained for each cell.

Steady-State Inactivation: Steady-state fast inactivation (h_{∞}) was assayed with 500ms pre-pulses from -130 to 5mV (in 5mV increments) followed by a 20ms test pulse to -20mV to assess channel availability. Currents at each pre-pulse were normalized to the peak current. Data of normalized currents as a function of voltage was fitted with the single phase Boltzmann distribution, $\frac{I}{I_{max}} =$

$$\left(\frac{1}{1 + e^{(V_m - V_{1/2})/k}} \right), \text{ from which the half-point of inactivation } (V_{1/2}) \text{ and slope factor } (k)$$

were obtained for each cell. V_m corresponded to the prepulse voltage.

Additionally, current densities were estimated for each individual recording by dividing the peak transient currents obtained from h_{∞} by the membrane capacitance.

Recovery from Inactivation: Recovery from inactivation was assayed with a two-pulse protocol that depolarized the membrane to -20mV for 20ms from the holding potential (-100mV). The time between the pulses was increased by an additive 2^n factor, where n=sweep number. At each time point the peak current measured in the second pulse (I_2) was normalized to the peak current measured in the first pulse (I_1), yielding the fraction of sodium channels available. The fraction available ($\frac{I_2}{I_1}$) was plotted as a function of time (t) and fitted to a double exponential equation, $\frac{I_2}{I_1} = A_0 + A_{fast}e^{-t/\tau_{fast}} + A_{slow}e^{-t/\tau_{slow}}$, from which we obtained the recovery time constants for the fast (τ_{fast}) and slow component (τ_{slow}) and compared between groups.

Accumulation of long-term inactivation: Cells were assayed with a four-pulse protocol, as previously described (175), to measure long-term inactivation. Each pulse depolarized the membrane to -20mV for 16ms from a holding potential of -90mV with -90mV 40ms interpulse recovery phases between each depolarization pulse. Currents measured at each pulse were normalized to peak current to yield percentage of sodium channels available. The % of channels available was plotted as a function of depolarization cycle (i.e., pulse number).

Resurgent Current: Cells were assayed with a two-pulse protocol that initially depolarized the membrane to +30mV for 20ms from the holding potential (-100mV), followed by repolarizing voltage steps from +15mV to -85mV for 100ms in -5mV increments to test for resurgent currents; cells were then returned

to their holding potential (-100mV). Resurgent currents display unique characteristics of slow onset and slow decay along with a non-monotonic I/V relationship. Currents that did not meet these characteristic were classified as negative for resurgent currents. Based on these criteria, the percentage of DRG that were positive/negative for resurgent current was quantified for each condition. Resurgent current amplitudes were measured after 3.0ms into the repolarizing pulse to avoid contamination from tail currents. Peak resurgent current amplitude at each test potential was normalized to peak transient current (obtained from the h_{∞} protocol) and expressed as a percentage of the peak transient current. Normalized resurgent current amplitude was plotted as a function of voltage.

Statistics

Data are presented as mean \pm standard error of the mean (SEM). The data were tested for a Gaussian distribution fit with the D'Agostino & Pearson omnibus normality test. Data that fit a Gaussian distribution were compared with a parametric Student's t-test at a 95% level of confidence ($\alpha=0.05$). Data that did not fit Gaussian distribution were compared with a non-parametric Mann-Whitney Test with 95% level of confidence ($\alpha=0.05$). The Chi-square test (X^2 test) was used to compare the frequency distribution of neurons that were positive or negative for resurgent current at a 95% level of confidence ($\alpha=0.05$).

Results

Biophysical properties of Nav1.6r with FHF2A and FHF2B

We first examined if, in DRG neurons, FHF2A could mediate the characteristic long-term inactivation that has been reported in other cells with FHFAs variants (163, 175). Primary cultures of DRG neurons were biolistically co-transfected with Nav1.6r and tagged-FHF2A or tagged-FHF2B. As a negative control, only the tag (pmTurquoise2; fluorescent protein) was transfected. Whole cell voltage clamp recordings of isolated Nav1.6r currents were obtained by pharmacological (addition of 500nM TTX) and genetic (Nav1.8shRNA) inhibition of endogenous DRG sodium currents. Long-term inactivation was measured using a four-pulse step protocol (see Methods). Representative traces obtained with this long-term inactivation assay are shown in Figure 22A for each group. Overexpression of FHF2A increased accumulation of Nav1.6r in long-term inactivated states, consistent with previous reports (163, 175). FHF2A progressively decreased Nav1.6r availability with each depolarization cycle relative to control (Figure 22B, minimum sodium channel availability $p < 0.0001$: FHF2A $72 \pm 3\%$, $n=18$; Control $90 \pm 2\%$, $n=28$), whereas, FHF2B did not (FHF2B $91 \pm 2\%$, $n=13$).

We also examined how FHF2A and FHF2B alter other biophysical properties of Nav1.6r in DRG neurons since in different cell backgrounds the

interaction of FHF2s with VGSCs have been reported to alter current density, inactivation, activation and recovery (161). Using the current-voltage (I/V) protocol for steady state activation (see Methods) we quantified the peak current density and the voltage-dependence of activation. Overexpression of FHF2A or FHF2B did not alter peak current density of Nav1.6r relative to control (current density $p=0.10$ and $p=0.18$ respectively: FHF2A $2.9 \pm 0.2\text{nA/pF}$, $n=25$; FHF2B $1.6 \pm 0.3\text{nA/pF}$, $n=16$; control $2.0 \pm 0.2\text{nA/pF}$, $n=11$). FHF2A did shift the voltage-dependence of activation to positive potentials by $\sim 10\text{mV}$ (Figure 21C), whereas FHF2B did not, relative to control (Table 4). Consistent with previous reports (157, 162, 163, 254), FHF2A and FHF2B shifted the voltage-dependence of inactivation to more depolarized potentials (Figure 22D). FHF2A slowed recovery from inactivation, whereas, FHF2B enhanced recovery from inactivation relative to control (Figure 22E). Table 4 shows a summary of recovery, inactivation, activation and current density data.

Figure 22: Biophysical properties of Nav1.6r modulated by FHF2A and FHF2B. DRG neurons were transfected with Nav1.6r and FHF2A, FHF2B or fluorescent protein tag (control). **A**, Representative traces of cycle-dependent reduction as a measure of accumulation of long-term inactivation (LTI) for control (black), FHF2A (blue) and FHF2B (purple) groups. **B**, The percentage of channels available as a function of depolarization cycle shows overexpression of FHF2A (n=19) increased accumulation of long-term relative to control (n=28), whereas, FHF2B (n=13) did not. **C**, Normalized conductance (G/Gmax) as a function of voltage shows that FHF2A (blue squares, n=16) overexpression shifted the voltage-dependence of activation relative to control (black circles, n=25). No change is observed for FHF2B overexpression (purple diamonds, n=11) relative to control. **D**, Normalized current (I/Imax) as a function of voltage shows that voltage-dependence of inactivation was shifted to positive potentials in FHF2A (n=19) and FHF2B (n=13) groups relative to control (n=27). **E**, Fraction of channels available as a function of time shows FHF2A (n=19) overexpression greatly slowed recovery from inactivation relative to control (n=15), whereas, FHF2B (Inset, n=12) enhanced channel recovery. Asterisks (*) represent $p < 0.0001$ obtained from Student's t-test. Data are mean \pm SEM

	Activation		Inactivation		Recovery

Table 4: Biophysical properties of Nav1.6r in control, FHF2A and FHF2B groups.

Abbreviations are: τ , time constant; k, slope factor of activation or inactivation curve; $V_{1/2}$, midpoint voltage of activation or inactivation curve. Groups were compared to control using Student's t-test (parametric) or Mann-Whitney U Test (non-parametric). * $p < 0.05$ (vs. control); # $p < 0.005$ (vs. control); $^\dagger p < 0.0001$ (vs. control). Data are mean \pm SEM and n is the number of cells from which recordings were obtained.

Differential modulation of fast resurgent currents by FHF2A and FHF2B

We next investigated the modulation of resurgent current by these FHF2 isoforms. To do so, we used a two-pulse protocol described in the Methods section. Resurgent current amplitudes were normalized to peak transient current (obtained from the steady-state inactivation protocol) and expressed as the percentage of the peak current. Representative traces of resurgent currents are shown in Figure 23A for each group. Overall FHF2A reduced the fraction of neurons positive for resurgent current (χ^2 test $p < 0.05$) whereas FHF2B did not, relative to control (Figure 23B). FHF2A also reduced resurgent current amplitude relative to control (Figure 23C Peak Resurgent Current Amplitude $p < 0.005$: FHF2A $0.371 \pm 0.21\%$, $n=18$; Control $1.14 \pm 0.27\%$, $n=29$). FHF2B exhibited the opposite effect, doubling peak resurgent current amplitude relative to control ($p < 0.05$: FHF2B $2.41 \pm 0.22\%$, $n=13$).

Figure 23: FHF2A and FHF2B differentially regulate fast resurgent currents. **A**, Representative traces of Nav1.6r mediated resurgent currents obtained from cultured DRG neurons with corresponding peak resurgent currents highlighted for control (black), FHF2A overexpression (blue) and FHF2B overexpression (purple) conditions. **B**, The distribution of resurgent current positive (+INaR)/resurgent current negative (-INaR) DRG neurons was not different with FHF2B (n=13) overexpression relative to control (n=29). FHF2A (n=18) overexpression significantly decreased the percentage of DRG neurons that generated resurgent currents relative to control ($p < 0.0005$, χ^2 test). **C**, Normalized resurgent current amplitude as a function of voltage shows FHF2A overexpression (blue squares) decreased resurgent current amplitude in a range of voltages relative to control (black circles). In contrast, FHF2B overexpression (purple triangles) increased resurgent current amplitude in a range of voltages. Asterisks (*) represent $p < 0.05$ (vs control) obtained from Student's t-test. Data are mean \pm SEM.

FHFA peptide replicates long-term inactivation effects and reduces Nav1.6r
resurgent currents

FHF2A has two known potential interactions that might contribute to Nav1.6r modulation: 1) binding to the C-terminus of sodium channels and 2) long-term inactivation particle binding (presumably to the inner pore region). We hypothesized that FHF2A's long-term inactivation particle is the main contributor for the observed negative regulation of fast resurgent currents. To explore this possibility, we used a peptide (FHFA) corresponding to amino acid residues 2-21 in the FHF2A protein, which was previously identified as the long-term inactivation particle (175). FHFA peptide (1mM) was added to the internal recording solution as described by Dover et al, 2010. DRG neurons were transfected with Nav1.6r and currents were isolated by pharmacological (500nM TTX) and genetic (Nav1.8shRNA) inhibition of endogenous sodium currents as described in the Methods. Voltage clamp recordings were obtained five minutes after dialysis of the internal solution in the presence or absence of the peptide. Using the protocols previously described we examined current density, activation, inactivation, recovery, long-term inactivation and resurgent currents. Representative traces of accumulation of long-term inactivation are shown in Figure 24A-B. Dialysis of the FHFA peptide greatly increased the accumulation of Nav1.6r in long-term inactivated state (Figure 24C, minimum sodium channel availability $p < 0.0001$: +FHFA $29 \pm 3\%$, $n=15$; -FHFA $84 \pm 2\%$, $n=16$). Recovery from inactivation was significantly slowed in the +FHFA peptide group relative to

the -FHFA peptide group (Figure 24D and Table 5). Addition of the FHFA peptide did not alter Nav1.6r current density relative to control (current density $p=0.08$: +FHFA Peptide $1.7 \pm 0.4\text{nA/pF}$, $n=16$; -FHFA Peptide $0.9 \pm 0.1\text{nA/pF}$, $n=14$). The voltage-dependence of activation or voltage-dependence of inactivation, was not different between +FHFA peptide group and -FHFA peptide control (Table 5).

Representative traces of peak Nav1.6r resurgent currents are shown in Figure 24E. The amplitudes of the resurgent currents were normalized to peak sodium current and are expressed as the percentage of peak current. The +FHFA peptide group exhibited reduced resurgent current amplitudes relative to the -FHFA peptide group (Figure 24F, peak resurgent current $p<0.05$: +FHFA Peptide 0.88 ± 0.3 , $n=16$; -FHFA Peptide $1.9 \pm 0.6\%$, $n=15$). The fraction of resurgent current positive neurons was also greatly reduced in the +FHFA peptide group (χ^2 test $p<0.005$: 20%, $n=15$) relative to control -FHFA peptide (69%, $n=16$).

Figure 24: FHFA peptide exhibits long-term inactivation activity and recapitulates resurgent current reduction effects. Nav1.6r currents were isolated in DRG neurons and recordings were obtained in the presence (+) or absence (-) of FHFA peptide in the recording pipette. Representative traces of cycle-dependent reduction as a measure of accumulation of long-term inactivation (LTI) are shown for -FHFA peptide group (**A**, black) and +FHFA peptide group (**B**, pink). **C**, The percentage of channels available as a function of depolarization cycles shows that addition of the FHFA peptide (black circles, n=15) significantly increased accumulation of channels in long-term inactivated states relative to -FHFA peptide group (pink squares, n=14). **D**, Recovery from inactivation was greatly slowed in +FHFA peptide group (n=15) relative to -FHFA peptide group (n=14). **E**, Representative traces of Nav1.6r mediated resurgent currents with peak currents highlighted for -FHFA peptide (black) and +FHFA peptide (pink) groups. **F**, Compared to -FHFA peptide (black circles, n=15), addition of the FHFA peptide (pink squares, n=16) reduced resurgent current amplitude. Note resurgent currents were normalized to peak transient currents and plotted as a function of voltage. Asterisks (*) represent p < 0.05 obtained from Student's t-test. Data are mean \pm SEM.

Modulation of Nav1.6r by chimeric constructs of Nav β 4 and FHF2A

The FHF2A long-term inactivation particle is potentially inhibiting fast resurgent currents by competing with the open channel blocker for the open channel state. Our previous reports suggest that Nav β 4 is likely the main open channel blocker in DRG neurons (203). Therefore, we investigated if replacing the proposed open channel blocker sequence in Nav β 4 with FHF2A's long-term inactivation sequence would transfer the long-term inactivation activity and reduce resurgent currents in DRG neurons. Conversely, we replaced the long-term inactivation sequence in FHF2A with the open channel blocker in the Nav β 4 protein and hypothesized that this construct would increase resurgent current. The sequences were codon optimized and synthetically made (see Methods). The resulting chimeric constructs were named F2A(β 4) for the FHF2A protein containing the Nav β 4 open channel blocker sequence and β 4(F2A) for the Nav β 4 protein containing the FHF2A long-term inactivation sequence (Figure 25). Both constructs were tagged at the C-terminus with a fluorescent protein, pmTurquoise2, to verify expression. DRG neurons were biolistically transfected with Nav1.6r and one of the chimeric constructs. As a control, tag only was expressed instead of a chimeric subunit. Nav1.6r currents were isolated by pharmacological (500nM TTXR) and genetic (Nav1.8shRNA) inhibition of endogenous sodium currents as previously described. Using the recording protocols previously described we examined the biophysical properties of Nav1.6r with co-expression of β 4(F2A) or F2A(β 4) and investigated if the

chimeric constructs modulated resurgent currents. Representative traces of accumulation of long-term inactivation for each group are shown in Figure 26A. $\beta 4(F2A)$ slightly increased the accumulation of long-term inactivation relative to control (Figure 26B: minimum sodium channel availability $p < 0.05$: $\beta 4(F2A)$ $84 \pm 2\%$, $n=12$; Control $89 \pm 2\%$, $n=14$), whereas, $F2A(\beta 4)$ did not alter accumulation of long-term inactivation ($88 \pm 2\%$, $n=9$). Expression of either chimera, $\beta 4(F2A)$ or $F2A(\beta 4)$ did not alter the current density relative to control (current density $p=0.8$ and $p=0.4$ respectively: $\beta 4(F2A)$ $1.6 \pm 0.3 \text{ nA/pF}$, $n=12$; $F2A(\beta 4)$ $1.1 \pm 0.3 \text{ nA/pF}$, $n=9$; control $4.2 \pm 2.6 \text{ nA/pF}$, $n=14$). In a similar pattern as seen with FHF2A, $F2A(\beta 4)$ expression shifted the voltage-dependence of activation (Figure 26C) and inactivation (Figure 26D) of Nav1.6r to positive potentials by 5mV relative to control, whereas $\beta 4(F2A)$ did not alter either (Table 6). Expression of $F2A(\beta 4)$ enhanced Nav1.6r recovery from steady-state inactivation relative to control (Figure 26E Inset). $\beta 4(F2A)$ did not slow or enhance Nav1.6r recovery from inactivation relative to control (Figure 26E and Table 6).

Figure 25: Chimeric constructs of FHF2A and Navβ4. **A**, Illustration of FHF2A and Navβ4 subunits. The Navβ4 subunit consists of an extracellular N-terminal domain, single transmembrane and a cytosolic domain C-terminal domain. The cytosolic domain contains a sequence of amino acids proposed to mediate open channel block that generate resurgent currents (red sphere represents β4 peptide sequence, amino acids 183-203(197, 199)). The FHF2A subunit is a cytosolic protein, which contains a core region homologous to all FHF with a C-terminal epitope that enables interaction with the cytoplasmic C-terminal region of sodium channels (160). Distinct from its FHF2B counterpart, the FHF2A N-terminus sequence is much longer and contains a sequence identified as the long-term inactivation particle (yellow sphere, amino acids 1-20 (175)). Arrow between the subunits highlights the region that was exchanged between these subunits to generate the chimeric constructs. **B**, Illustration of the resulting chimeric constructs. The β4(F2A) contains all components of the Navβ4 subunit with the exception of β4-peptide sequence, which was replaced with long-term inactivation particle sequence. The F2A(β4) contains all domains of the FHF2A protein except the long-term inactivation particle, which was replaced with the β4 peptide sequence. *Inset*, depicts the figure legend for the β4-peptide and long-term inactivation particle with the corresponding amino acid sequence.

Figure 26: Biophysical properties of Nav1.6r modulated by $\beta 4$ (F2A) and F2A($\beta 4$) chimeras. **A**, Representative traces of cycle-dependent reduction as a measure of long-term inactivation (LTI) for Nav1.6r isolated currents in DRG neurons with co-expression of fluorescent tag (control, black), F2A($\beta 4$) (green) and $\beta 4$ (F2A) (orange). **B**, The percentage of channels available as a function of depolarization cycle shows increased accumulation of long-term inactivation for $\beta 4$ (F2A) group (orange squares, $n=12$) relative to control (black circles, $n=16$), whereas no difference is observed for F2A($\beta 4$) group (green triangles, $n=8$) relative to control. **C**, Normalized conductance as a function of voltage shows that co-expression of F2A($\beta 4$) ($n=8$) shifted the voltage-dependence of activation to positive potentials relative to control ($n=14$), whereas, no change is observed for the $\beta 4$ (F2A) group ($n=12$). **D**, Normalized current as a function of voltage shows that co-expression of F2A($\beta 4$) ($n=9$) shifted the voltage-dependence of steady-state inactivation to positive potentials relative to control ($n=14$), whereas, no change is observed for the $\beta 4$ (F2A) group ($n=12$). **E**, Fraction of current available as a function of time shows that recovery is not significantly altered with co-expression of either chimera $\beta 4$ (F2A) ($n=12$) or F2A($\beta 4$) ($n=9$) relative to control ($n=14$). Differential modulation of fast resurgent currents by F2A(β 4)
and β 4(F2A) chimeras

We next examined Nav1.6r-mediated resurgent currents. Resurgent current amplitude was normalized to the peak sodium current obtained from the steady-state inactivation protocol and expressed as the percentage of peak current. Representative traces of resurgent currents for each condition are shown in Figure 27A. Figure 27B shows the distribution of resurgent current positive and resurgent current negative neurons for each condition. Overall the percentage of resurgent current positive neurons was not significantly different with expression of β 4(F2A) or F2A(β 4) relative to control ($p=0.30$ and $p=0.52$, respectively). The percentage of resurgent current positive neurons was 33% for β 4(F2A), 67% for F2A(β 4) and 53% for control. However, F2A(β 4) expression increased the resurgent current amplitude by three-fold relative to control (Figure 27C peak resurgent current $p<0.05$: F2A(β 4) $3.1 \pm 0.8\%$, $n=9$; Control $1.2 \pm 0.4\%$, $n=15$). In contrast, β 4(F2A) reduced the amplitude of the resurgent current by two-fold (β 4(F2A) $p<0.05$ $0.4 \pm 0.2\%$, $n=12$).

Figure 27: $\beta 4$ (F2A) and F2A($\beta 4$) differentially modulate fast resurgent currents. **A**, Representative traces of Nav1.6r resurgent currents obtained from cultured DRG neurons with corresponding peak resurgent currents highlighted for control (black), $\beta 4$ (F2A) (orange) and F2A($\beta 4$) (green) groups. **B**, Neither co-expression of $\beta 4$ (F2A) (n=12) nor co-expression of F2A($\beta 4$) (n=9) altered the distribution of resurgent current positive (+INaR)/resurgent current negative (-INaR) DRG neurons relative to control (n=16). **C**, Resurgent current amplitude was decreased with co-expression of $\beta 4$ (F2A) (orange squares, n=12) in a range of voltages relative to control (black circles, n=15). In contrast, co-expression of F2A($\beta 4$) (green triangles, n=9) chimera increased resurgent current amplitude in a range of voltages relative to control. Note that resurgent currents were normalized to peak transient currents and plotted as a function of voltage. Asterisks (*) represent p < 0.05 obtained from Student's t-test. Summary data are mean \pm SEM.

Inflammation causes differential effects on FHFAs and FHF2B isoforms

The results of overexpression of FHF2A and FHF2B, FHFA peptide and chimeric constructs suggest that the FHF2A and FHF2B isoforms regulate resurgent currents and may contribute to pain pathologies. Therefore, we chose to examine FHF2A and FHF2B expression in a radicular pain model in which we previously reported increased resurgent currents in a collaboration study with Dr. J-M. Zhang (242). In this model, localized inflammation of the DRG (LID) causes persistent mechanical hypersensitivity that starts as soon as post operative day 1 (14, 120, 121, 242). To examine FHF2A and FHF2B expression, Sprague Dawley Rats were injected with zymosan at a 2mg/mL concentration near L4 and L5 DRG in one side of the spine (see Methods). Sham operated rats that underwent the same procedure with the exception of the injections were used as a control. At post operative day 5, L4/L5 ipsilateral DRG were harvested from LID and Sham operated animals. FHFA and FHF2B levels were examined in primary DRG cultures with immunocytochemistry. One caveat with the FHFA antibody used is that it is not selective to the FHF2A isoform, because it targets the long-term inactivation particle which is highly conserved between all FHFAs. However, in adult DRG neurons, FHF4A is not expressed and FHF1A is downregulated in adulthood (164). FHF1A contains a nuclear localization signal that is functional in DRG neurons and targets the protein to the nucleus (164). In contrast, the nuclear localization signal for FHF2A is predicted to be inactive since staining is limited to the cell periphery and not detected in the nucleus in adult DRG neurons

(163). Therefore, given that our model uses adult DRG neurons we expect that cross-reaction is minimal and likely most of the antibody signal is reflecting FHF2A expression. Representative images of FHF2A staining are shown in Figure 28A-B. Inflammation of the DRG reduced FHF2A levels relative to Sham control (Figure 28C, FHF2A Mean Intensity $p < 0.0001$; LID $13.0 \pm 0.3\text{AU}$, $n=1989$, Sham $24.8 \pm 0.8\text{AU}$, $n=1116$). In contrast, FHF2B expression was modulated in the opposite direction as FHF2A. Representative images of FHF2B staining are shown in Figure 28D-E. FHF2B was upregulated in the LID group relative to Sham control (Figure 28F, FHF2B Mean Intensity $p < 0.0001$; LID $29.5 \pm 1.6\text{AU}$, $n=1121$, Sham $21.04 \pm 0.4\text{AU}$, $n=1164$).

Figure 28: FHFA and FHF2B levels are differentially altered after local inflammation of the DRG. Examples of immunocytochemical staining against FHFAs in primary cultured DRG neurons from control (sham operated, **A**) and induced local inflammation of the DRGs (LID, **B**) animals at post operative day 5. **C**, DRG neurons from LID animals (n=1989) exhibited an increase in FHFA signal relative to sham control (n=1116). Examples of immunocytochemical staining against FHF2B in primary cultured DRG neurons from sham (**D**) and LID (**E**) animals at post operative day 5. **F**, DRG neurons from LID animals (n=1164) exhibited a decrease in FHF2B signal relative to sham control (n=1121). Five animals per group were examined. Asterisks (*) represent $p < 0.0001$ obtained from Student's t-test. Summary data are mean \pm SEM. Scale bar 50 μ m.

Discussion

In this study we show that FHF2A and FHF2B differentially regulate resurgent sodium currents in DRG sensory neurons. The first component of the third aim hypothesis was that FHF2A limits the capacity of sensory neurons to generate fast resurgent currents by mediating long-term inactivation. Three main findings support this hypothesis. First, overexpression of FHF2A reduced the resurgent current and increased the accumulation of channels in inactivated states resulting in delayed channel recovery. Secondly, a peptide derived from FHF2A's long-term inactivation particle recapitulated the reduction in resurgent current generation and the enhancement of long-term inactivation. The peptide did not modulate the voltage-dependence of inactivation and activation as seen with full length FHF2A suggesting these changes do not account for negative regulation of resurgent current. Thirdly, the F2A(β 4) chimera (in which the long-term inactivation particle was replaced with Nav β 4's open channel blocker sequence) did not negatively regulate resurgent currents nor did it induce long-term inactivation. The chimera produced the opposite effect, an enhancement in resurgent current modulation suggesting this region is key for FHF2A's resurgent current modulation.

The second component of our hypothesis was FHF2B increases resurgent currents by delaying inactivation. Our results support this hypothesis. FHF2B increased resurgent currents, shifted the voltage-dependence of inactivation to

positive potentials and enhanced recovery from inactivation. FHF2B's inability to mediate long-term inactivation while still shifting inactivation to positive potentials likely increased the accessibility of the putative open channel blocker. The faster recovery observed with overexpression of FHF2B supports this possibility, since recovery when the channel undergoes open channel block is reported to occur in a shorter time scale than channel recovery from fast inactivation (178). An alternative explanation is that FHF2B displaces the endogenous negative regulation exerted by FHF2A because all FHFs are predicted to bind to a conserved region within the C-terminus of VGSCs (160). FHF2A is expressed in neurons of all size classes and is particularly predominant in small diameter neurons (163). The transfected neurons examined in these studies were mostly in the small diameter range. Therefore, it is plausible that displacement of endogenous FHF2A by exogenous FHF2B contributes to some extent to FHF2B's positive regulation of fast resurgent currents.

Based on previous reports, the potential mechanism for FHF2A negative regulation is competition of the long-term inactivation particle with the Nav β 4 open channel blocker activity (176, 203). The results from FHF2A and Nav β 4 chimeras partially support this hypothesis, however the implications of results obtained with these chimeric proteins is limited by a few caveats. Our assumption was that by replacing the peptide sequence of long-term inactivation with the open channel blocker and vice-versa the activity of these peptide sequences would be retained in the resulting chimera. However, the β 4(F2A) chimera failed

to delay channel recovery and produced only a very mild enhancement in accumulation of inactivated states; suggesting that the long-term inactivation particle is not fully functional in the chimeric construct. Therefore, the reduction in resurgent current observed with the expression of the $\beta 4(F2A)$ chimera is likely due to a dominant negative effect of an inactive Nav $\beta 4$, likely competing with wildtype Nav $\beta 4$ for α subunits. In a similar manner, there are two possible contributions underlying F2A($\beta 4$)'s resurgent current enhancement: 1) the Nav $\beta 4$ open channel blocker sequence is active in the chimera and/or 2) loss of the long-term inactivation particle allowed other changes in the voltage-dependence to favor the endogenous open channel blocker interaction as seen with FHF2B. To further explore the first possibility, we tested the F2A($\beta 4$) chimera in a Nav1.5 HEK cell line that does not generate resurgent current unless the $\beta 4$ -peptide is introduced. We found that indeed the F2A($\beta 4$) chimera mediated resurgent currents (Figure 29) in a Nav1.5 cell-line. This result favors the possibility that the F2A($\beta 4$) chimera retains open channel blocker activity. However, it would be simplistic to assume that the resurgent current enhancement is only due to this activity. It is likely a combined effect of removing a limiting determinant (i.e. long-term inactivation particle), adding an active open channel blocker sequence and the shift in voltage-dependence of inactivation contributing to the overall enhancement of resurgent current. Overall, results from $\beta 4(F2A)$ and F2A($\beta 4$) chimeras confirmed that the N-terminus of FHF2A and the C-terminus of Nav $\beta 4$ are important modulators of fast resurgent currents.

Figure 29: F2A(β 4) but not FHF2B induced fast resurgent currents mediated by Nav1.5 in HEK cells. HEK293 cells stably expressing Nav1.5 were transfected with tagged-F2A(β 4) or tagged-FHF2B. Non-transfected cells were used as a control. Resurgent currents were elicited with a standard resurgent current voltage protocol, in which cell membrane was initially depolarized to +30mV for 20ms, and then repolarized to voltages ranging from +15mV to -85 for 100ms in 5mV increments. **A**, Representative traces of Nav1.5 resurgent currents are shown for control (black), FHF2B (purple) and F2A(β 4) (green). Trace obtained at -40 mV is highlighted for each group. **B**, Resurgent current amplitude was normalized to peak transient current. F2A(β 4) (green triangles) generated a biphasic current voltage curve typically observed for resurgent currents, whereas, control (blue circles) or FHF2B (purple diamonds) did not. **C**, Effects of FHF2B and F2A(β 4) on Nav1.5's voltage-dependence of activation. The $V_{1/2}$ values are -47.5 ± 0.9 mV (control), -47.6 ± 0.3 mV (FHF2B) and -45.5 ± 0.4 mV (F2A(β 4)), respectively. **D**, Effects of FHF2B and F2A(β 4) on voltage-dependence of inactivation. The $V_{1/2}$ values are -92.4 ± 1.2 mV (control), -87.5 ± 0.5 mV (FHF2B) and -85.3 ± 1.0 mV (F2A(β 4)), respectively. The holding potential was -120 mV. Data are mean \pm SEM and $n=5$ for each group.

FHFs binding to the C-terminus of VGSC can cause changes in the biophysical properties of the VGSC (134). Expression of FHF2A, FHF2B or F2A(β 4) shifted the voltage-dependence of inactivation to positive potentials. Since the F2A(β 4) chimera lacks the long-term inactivation particle sequence yet retained the ability to cause shifts in voltage-dependence of activation and inactivation, the results suggest that these modulations are mainly an effect of the FHF2 core region binding to the C-terminus of Nav1.6. The shift of inactivation to positive potentials is consistent with previous reports of FHF2 binding to the C-terminus of different sodium channels including Nav1.6 (157, 160, 162, 163). FHF2A and F2A(β 4) also shifted activation to positive potentials. Since both F2A(β 4) and FHF2A but not FHF2B exerted this effect, it is most likely that the N-terminus region that is conserved between F2A(β 4) and FHF2A is responsible for this effect.

Interestingly, the chimeras generated for this study might serve as valuable tools for the study of resurgent currents in the future. The (β 4)F2A chimera did not significantly alter the voltage-dependence of activation or inactivation, recovery from inactivation, or current density. The main effect we detected was a significant reduction in resurgent current. As such, overexpression of this protein in animal models or in vitro studies might serve as a tool to selectively target resurgent currents. On the other hand, the F2A(β 4) chimera might serve as a tool to artificially induce fast resurgent currents. The applications for the F2A(β 4) might be limited since it alters other channel

properties. However, we envision that the F2A(β 4) chimera might be useful in high-throughput assays to identify compounds that might inhibit resurgent currents.

Overall our data suggest that FHF2A and FHF2B modulate resurgent currents in DRG neurons. The importance of this finding is more evident when we examine how these proteins are regulated in a radicular pain model induced by localized inflammation of the DRG. Our results show that after inflammation FHFA isoforms are downregulated, whereas FHF2B was upregulated. The change in expression of these isoforms likely contributes to the increased resurgent current generation and hyperexcitability reported in this model (116, 120, 242). The limitation of the antibody specificity precludes us from definitively attributing the effect solely to changes in the FHF2A isoform. However, the high conservation of the long-term inactivation particle between all FHFAs suggests that if other FHFAs were to interact with Nav1.6 they will likely have a similar negative regulation on resurgent currents. FHF modulation might also contribute to other pain pathologies. For example, two studies using cDNA arrays reported FHF2 cDNA levels downregulated with no change in FHF1 and FHF4 after peripheral nerve injury (165, 166). Using the Expression Atlas (255) from European Bioinformatics Institute and European Molecular Biology Laboratory we found that FHF1 and FHF2 levels are downregulated in DRG neurons after spinal nerve ligation, a chronic pain model (256). Which of the FHF1 and FHF2 isoforms contribute most to these changes is unknown. Our study suggests that

FHFs might prove to be novel targets for regulating fast resurgent current in DRG neurons and further studies might provide new insight into possible therapeutic strategies for pain.

SUMMATION AND FUTURE DIRECTIONS

Increased fast resurgent currents in peripheral sensory neurons have been implicated in several pain pathologies. However, our knowledge of how these currents are modulated in sensory neurons is limited. The main goal of this dissertation was to identify fast resurgent current modulators in order to address the gap in our knowledge and potentially devise new therapeutic or experimental strategies. We focused on Nav1.6 mediated currents because this isoform is the main carrier of fast resurgent currents (27). Thus, our findings may be particularly relevant to pain pathologies associated with Nav1.6 channel activity that contributes to DRG's hyperexcitability.

Nav β 4 and resurgent currents

The identity of the open channel blocker that mediates resurgent currents in DRG neurons was unclear. Results from the first aim of this dissertation suggest that Nav β 4 is the major open channel blocker in DRG neurons. Overexpression of Nav β 4 greatly increased resurgent currents, whereas, knockdown or overexpression of a mutant form of Nav β 4 decreased resurgent current generation. The Nav β 4 C-terminal mutant data suggests that in congruence with CNS studies, the C-terminal region of Nav β 4 is important for resurgent current generation (180, 197, 199). In contrast, our results suggest that Nav β 2 does not modulate fast resurgent currents.

Our interpretation of the results is limited because we did not directly examine if Nav β 2 or Nav β 4 associates with Nav1.6 in the DRG neuronal background. Future studies are needed to determine if Nav β 4 resurgent current modulation is due to association with Nav1.6. One potential approach to determine whether there is an association between these subunits, would be to use identified mutations at the N-terminus of Nav β 4 that disrupt association with α subunits (228, 230). If overexpression of an N-terminal Nav β 4 mutant that does not associate with Nav1.6 modulates resurgent currents this might suggest that Nav β 4's resurgent current modulation is independent of Nav1.6 association. An alternative approach would be to use pharmacological tools to determine the potential association of Nav β 2 or Nav β 4 with Nav1.6. For example, recent studies have found that Nav1.2 inhibition by ProTxII (a toxin isolated from the tarantula (257)) is disrupted by association of Nav β 2 or Nav β 4 (230, 231). It is unknown if the same effects are observed for Nav1.6 but would be an important avenue to explore. However, these studies might require a cell background that lacks robust expression of β -subunits. Biochemical assays such as co-immunoprecipitation of the β -subunit: α subunit complex in DRG tissue might be necessary to strengthen any findings.

Modulation of Nav1.6 by Nav β 4 may also be due to direct or indirect interaction of Nav β 4 protein fragments. β subunits are known substrates of proteases from the secretase family (Figure 30) (244). Sequential proteolysis can produce a variety of fragments. N-terminal cleavage generates a soluble IgG

extracellular fragment and a transmembrane C-terminal fragment (258). The C-terminal transmembrane fragment is further processed to yield a transmembrane fragment and a soluble C-terminal fragment (258, 259).

Figure 30: Schematic representation of secretase cleavage sites in β -subunits. The extracellular N-terminus region close to the transmembrane domain contains a cleavage site for β -site amyloid precursor protein-cleaving enzyme 1 (BACE1)(258, 260). Nav β 2 contains an additional α -secretase cleavage site at the N-terminus (259). The C-terminus juxtamembrane region contains a γ -secretase cleavage site(259).

A study by Huth et al, suggests that cleavage of Nav β 4 by β -site amyloid precursor protein-cleaving enzyme 1 (BACE1) modulates the decay of resurgent sodium current in cerebellar neurons(261). Several studies concur that Nav β 4 association with alpha subunits is dependent on the N-terminal domain of the beta subunit (198, 228, 230, 262). Thus, shedding of Nav β 4's extracellular domain by BACE1 cleavage would potentially destabilize the association with an alpha subunit (261). It is unclear if the resulting C-terminal transmembrane domain can interact with Nav1.6 or if further processing of the C-terminal fragment yields a soluble peptide with open-channel blocker activity.

Proteolytic fragments may also indirectly modulate sodium channels (244, 263). For example, the soluble C-terminal fragment of Nav β 2 translocates to the nucleus (263). It has been proposed that the nuclear fragment exerts transcriptional regulation of sodium channels by functioning as transcription factors (263). It is possible that Nav β 4 regulates Nav1.6 expression in this manner or may modulate transcription of factors that modulate channel activity. Further studies are needed to examine the potential modulation of Nav1.6 or resurgent currents by Nav β 4 proteolytic fragments in DRG neurons. Selective activators and inhibitors of different secretase enzymes may serve as tools to address this question (264).

Nav β 4 and nociception

In the second part of this dissertation we examined the effects of Nav β 4 knockdown in an inflammatory pain model. In the LID model, Nav1.6 has been proposed to contribute to mechanical hypersensitivity. However, it is unknown if fast resurgent currents are altered and if they contribute to the hyperexcitability of DRG neurons and mechanical hypersensitivity. Our results show that LID increases fast resurgent currents and transient currents in DRG neurons. Knockdown of Nav β 4 prevented the increase in fast resurgent current, excitability and mechanical sensitivity. Nav β 4 knockdown also reduced persistent currents. Our results suggests that in the LID model, Nav β 4's modulation of resurgent and persistent currents contributes to hyperexcitability . Fast resurgent currents are

proposed to increase the firing frequency of DRG neurons (17, 19, 196, 249, 265, 266). Persistent currents depolarize the membrane, decreasing the stimulus needed to trigger an action potential (73, 265, 267, 268). Together these changes, could enable the spontaneous burst firing similar to the pattern observed in LID DRG neurons (238, 269). Future studies are needed to confirm the contribution of resurgent currents and persistent currents with DRG neuronal simulations since selective inhibition through pharmacological methods is not currently feasible.

One of the limitation of our study, is that the we performed patch clamp studies in cultured DRG neurons which lacked axonal projections and nerve endings. While we did detect Nav β 4 upregulation in the soma and the axonal regions near the DRG, we did not examine if resurgent and persistent currents are also enhanced at the axon or nerve endings. Furthermore, we did not examine where spontaneous activity is initiated (i.e. at the soma or in other neuronal compartments). If spontaneous activity were to be generated at the neuronal soma, the action potentials generated may then be relayed to the periphery, spinal cord, or both. Transmission of action potentials toward the periphery may stimulate release of neurotransmitters and other chemical substances that in turn sensitize the nociceptive fibers to activation (270). On the other hand, constant release of neurotransmitters and other chemical mediators at the spinal cord may facilitate the activation of second order nociceptive neurons at the spinal cord (271, 272). In this manner, maladaptive changes at

the periphery or at the spinal cord may facilitate a nociceptive like-response to a normally innocuous stimulus. Future studies could examine the potential changes at the peripheral nerve endings or at the spinal cord in the LID model employing electrophysiological and immunohistochemical methods to elucidate these possibilities.

Although the location of spontaneous activity merits further examination, several studies have shown that spontaneous activity is key for the development of persistent pain (273-276). In particular, early blockade of afferent spontaneous activity (within 10 days of injury) in some models is sufficient to prevent the development of chronic mechanical and thermal hypersensitivity (119). Based on our results, agents that block both resurgent and persistent currents may be effective in reducing spontaneous activity. Our experimental LID paradigm in which $\beta 4$ -siRNA was injected at the time of inflammation, suggest that early blockade might be sufficient to prevent persistent mechanical hypersensitivity in this model. Future studies are needed to explore the therapeutic potential of agents that selectively target persistent and resurgent currents over the transient current that underlies the action potential upstroke. For example, a published collaboration study with R. Patel (277) suggests that cannabidiol, an active agent found in the cannabis plant, selectively targets persistent and resurgent currents. It would be important to determine if cannabidiol reduces spontaneous activity in the LID model and if it has a therapeutic effect. Alternatively, future studies might explore selective targeting of the Nav $\beta 4$ C-terminal region. The available Nav $\beta 4$

crystal structure might help identify compounds that target the Nav1.6 and Nav β 4 interaction (230).

A β fibers and the LID model

In the LID pain model, hyperexcitability is mainly observed in A β fibers. To devise the best therapeutic strategy, it is important that we understand how A β fibers contribute to the pathology. The role of A β fibers in nociception has been controversial because these fibers were initially thought to be mainly activated by non-noxious mechanic stimulation (82). Thus, A β fibers have been classified as low-threshold mechanoreceptors. However, there is intriguing evidence that suggests a population of A β fibers is activated by noxious mechanic or heat stimuli (82, 278-285). Therefore, a fraction of A β fibers have been identified as putative nociceptors or high-threshold fibers.

There are two main ascending pathways by which A β fibers could modulate nociceptive impulses from reaching the CNS and alter pain perception. The pathways are known as the lemniscal pathway and the spinothalamic pathway (286, 287). One way to distinguish between these two pathways is by identifying the second order neurons to which the DRG's CNS branch mainly projects. The lemniscal pathway second order neurons are located in the medulla. In contrast, spinothalamic second order neurons are located in spinal cord. Second order neurons then project to third order neurons in the thalamus.

Under non-pathological conditions, nociceptive impulses are relayed through the spinothalamic pathway (226, 287). In contrast, non-nociceptive (low threshold) DRG neurons are proposed to mainly relay impulses through the lemniscal pathway (286). A β fibers form part of the lemniscal pathway. It is important to note that this is a simplified scheme of the circuitry. In reality there are many collateral projections at each relay point. For example, A β fibers that send projections to the medulla also send collateral projections to the spinal cord (226, 286). Importantly, the collateral projections of low-threshold and high-threshold A β fibers may modulate the activation of the spinothalamic pathway at the spinal cord.

In the spinal cord there is a variety of neurons that can be divided by the lamina (anatomical surface division) they occupy (288). Classic DRG nociceptors (i.e. C-fibers and A δ -fibers) mainly project to lamina I-II nociceptive specific projection neurons (289, 290). Some DRG nociceptors may also project to wide-dynamic range (WDR) neurons, which are predominantly located in lamina V (226, 291, 292). WDR neurons can respond to a variety of stimuli intensities (low-threshold and high-threshold) (292). Nociceptive impulses from DRG neurons can be relayed by WDR or projection neurons through the spinothalamic pathway (226, 292). Lemniscal collaterals projections at the spinal cord can display different projection patterns. Putative A β nociceptors collaterals project to lamina I through V in a “flame-shaped” aspect (279-281). Thus, it has been proposed that these putative A β nociceptor projections may directly activate second order

nociceptive neurons at the spinal cord in lamina I-II or V, relaying impulses through the spinothalamic tract. However, it is not clear which neurons A β nociceptors communicate with at the spinal cord and if the net effect is inhibitory or excitatory. In contrast, low threshold A β mechanoreceptors collaterals mainly project to lamina III-V (and lamina II to a lesser extent) stimulating interneurons that activate and inhibit nociceptive neurons (291). The net effect of low threshold A β collaterals reduce the probability of nociceptive impulses from being relayed to the thalamus by activating inhibitory interneurons (293). It is proposed that activation of low threshold mechanoreceptors reduces the perception of pain by generating a segmental control or gate at the spinal cord level. Melzack and Wall introduced this concept in the gates control theory of pain (294, 295). They proposed that at each relay point, “gates” modulate the successful transmission of the nociceptive impulses to the next relay point. For example, descending pathways from the brain to the spinal cord can activate inhibitory interneurons at the spinal cord (293, 296-298).

Further studies are needed to explore which population of A β fibers might contribute to LID pain. If hyperexcitability of low threshold A β fibers are responsible for mechanical hypersensitivity then the normal circuitry may have been altered. One possibility is that inhibition control at the spinal cord is somehow compromised. Several studies have found a reduction in inhibitory signaling at the spinal cord in some pain conditions, although the mechanism is not clear (299-302). Other studies have suggested that a substantial portion of

non-nociceptive A-fibers sprout connections to laminae associated with nociceptive signaling, i.e. Lamina II (303-305). However, concerns regarding the selectivity of the neuronal tracers have questioned the interpretation of the results (306, 307). A more robust study, using neuronal tracers and selective markers, found a small portion of A-fibers sprout contacts into lamina II (308). It is possible that these abnormal contacts activate nociceptive specific neurons within lamina II overriding the inhibitory input. Interestingly, several studies have suggested that Nav β 4 and Nav β 4 proteolytic fragments promote neurite outgrowth (146, 147, 196). Future studies are needed to explore if upregulation of Nav β 4 promotes sprouting of A β fibers. On the other hand, if hyperexcitability of nociceptive A β fibers contributes to mechanical hypersensitivity, this hyperexcitability may produce changes at the peripheral nerve endings or second order neurons at the spinal cord facilitating activation of the spinothalamic pathway as previously discussed. Further studies are required to elucidate how the A β fiber circuitry contributes to nociception under normal and LID conditions.

FHF2 and resurgent currents

Resurgent currents are observed in a subpopulation of DRG neurons (27), raising the possibility of endogenous negative regulators which restricts resurgent current generation (27). Our results suggest that FHF2A negatively regulates resurgent currents. We identified the long-term inactivation sequence (or particle) in the N-terminus of the FHF2A protein as being important for

FHF2A's negative regulation. The chimeric construct that lacked the long-term inactivation particle failed to negatively regulate resurgent currents. Furthermore, a peptide derived from FHF2A's long-term inactivation particle recapitulated negative regulation of resurgent currents. Based on our results it is possible that in neurons where FHF2A is abundant, resurgent currents may be repressed. In contrast, FHF2B, which lacks the long-term inactivation particle, greatly increased resurgent currents. This effect is likely mediated by FHF2B modulation of fast inactivation to positive potentials, which may increase the probability of the open channel blocker to bind to the sodium channel. The core regions of FHF2A and FHF2B bind at the same site in the C-terminus of the alpha subunit. Therefore, it is possible that the ratio of FHF2A and FHF2B levels may regulate the degree of fast resurgent current generation in a given DRG neuron.

However, the interpretation of our results is limited since we mainly used an overexpression approach of FHF2 isoforms and chimeric constructs. Overexpression of a given subunit may induce an interaction that may not endogenously occur otherwise. Therefore, different experimental approaches are required to provide a more complete picture. One potential approach would be to couple single cell analysis with electrophysiological recordings. Using this approach, we could determine if a given DRG neuron generates resurgent currents and what are the corresponding levels of FHF2A, FHF2B, Nav β 4. If our model is correct, FHF2A levels would be negatively correlated with resurgent current amplitude. In contrast, we predict that FHF2B and Nav β 4 levels would be

positively correlated with resurgent current amplitude. Alternatively, in-vivo knockdown of FHF2A or FHF2B would allow us to examine the effects on endogenous fast resurgent current.

In the LID pain model, we found that FHFA isoforms are upregulated, whereas, FHF2B is downregulated. Based on our overexpression results of the individual proteins, downregulation of FHF2A and upregulation of FHF2B may contribute to the enhanced resurgent currents we detected in the LID model (see part 2 results). Further studies are needed to examine which FHFA isoforms are downregulated. One approach would be to use Reverse transcription polymerase chain reaction (RT-PCR) or in-situ hybridization with specific primer probes to examine mRNA levels. While mRNA levels do not always correlate to protein expression, this approach would allow us to distinguish between FHFA isoforms and overcome the limitation of lack of specificity of current available antibodies.

Future studies might also explore the individual contribution of FHF2A and FHF2B subunits to nociception. For example, it will be interesting to determine if FHF2A knockdown or overexpression of FHF2B is sufficient to induce pain associated behaviors. While we have identified these two potential players, other FHF's might also modulate Nav1.6 or other α subunits. In addition to FHF2, FHF1 and FHF4 are expressed in adult DRGs. FHF3 mRNA is detected in embryonic DRG but expression has not been studied in adult DRG neurons (309). There is always a possibility that expression of these isoforms is modulated in specific

pathophysiologies. Additionally, there is some evidence that suggests FHF2s interact with other partners such as kinases (150-152) and calcium channels (310) in CNS and cardiomyocytes. Therefore, it is possible that FHF2 modulation in DRG neurons alters other targets and may also contribute to pain pathologies. Further studies are necessary to determine such possibilities and provide more insights into FHF2s potential role in peripheral sensory neurons.

FHF2A and FHF2B as potential therapeutic targets

Based on our findings FHF2A and FHF2B may be useful targets for therapeutic interventions in the LID model. One potential strategy for a therapeutic intervention would be to disrupt FHF2B interaction with Nav1.6. We hypothesize that FHF2B disruption with Nav1.6 attenuates the increase in resurgent currents and might decrease hyperexcitability observed in the LID model. However, selective disruption of FHF2B interaction with the C-terminus of Nav1.6 may prove to be difficult since the core binding region for Nav1.6 is conserved between FHF2A and FHF2B. Inadvertent disruption of the FHF2A interaction with Nav1.6 might end up exacerbating hyperexcitability by further reducing long-term inactivation.

An alternative strategy for a therapeutic intervention would be to increase FHF2A's long-term inactivation activity. We hypothesize that increasing long-term inactivation activity would reduce resurgent current generation and

hyperexcitability. Future studies might explore in-vivo overexpression of FHF2A in the LID model. An alternative approach would be to inject the long-term inactivation particle (175) in the form of a cell-penetrating peptide. Our preliminary in-vitro results with this approach are promising (Figure 31). The FHFA peptide sequence corresponding to FHF2A's long-term inactivation particle (175) was coupled with a transactivator of transcription (tat) motif to yield tatFHFA, a predicted cell membrane penetrating peptide (311). The tatFHFA peptide effectively reduced spontaneous activity in DRG neurons cultured from LID animals at POD5 (Figure 31A-B). In contrast, no spontaneous activity was observed in DRG neurons cultured from sham animals. Interestingly, the tatFHFA peptide also reduced spontaneous activity from DRG neurons transfected with Nav β 4 (Figure 31C-D). Further studies are needed to confirm these results with additional controls such as a tat only peptide. Additional studies may also explore if tatFHFA is selective to Nav1.6. We speculate that it might not be. Therefore, one concern is that tatFHFA might have side effects that limit its therapeutic potential by targeting VGSCs in other parts of the body such as the CNS, heart or muscle tissues. For example, resurgent currents play a prominent role in the activity of cerebellar Purkinje neurons (17, 18, 167, 210). Reduction of cerebellar resurgent currents mediated by tatFHFA might impact motor coordination. Thus preliminary studies might explore the best dose and delivery method to minimize these side effects. Once optimized and proper controls are established, it will be interesting to see if the tatFHFA peptide can reduced hypersensitivity in the LID model or other pain models (16, 26).

Figure 31: Preliminary results of tatFHFA peptide. **A**, Representative trace of spontaneous activity recorded from cultured DRG neurons from a post operative day 5 animal that underwent LID surgery. No spontaneous activity was observed in sham control. **B**, Spontaneous activity is abolished after a 20min incubation with tatFHFA peptide at a 1mM concentration. **C**, Representative trace of spontaneous activity recorded from DRG neurons transfected with Nav β 4. **D**, After 20 min incubation with tatFHFA Nav β 4 mediated spontaneous activity is abolished. Representative traces correspond to one electrode (n=1) from a multielectrode array unit which records extracellular activity from multiple neurons.

General Conclusions

Overall, this dissertation addressed key questions regarding the modulation of resurgent currents in DRG neurons. The results of this dissertation have provided key insights into how resurgent currents are modulated in normal and pathophysiological conditions such as inflammation. Our results can be integrated into a new working model for resurgent current modulation in DRG neurons (Figure 32), in which Nav β 4 mediates resurgent currents, FHF2B enhances resurgent currents and FHF2A limits resurgent current generation. We propose these auxiliary subunits modulate resurgent currents and the biophysical

properties of Nav1.6 resulting in changes in neuronal excitability. In this manner, we propose that neuronal excitability can be modulated by enhancing or reducing resurgent currents. Regulatory auxiliary subunits may serve as alternative therapeutic targets to pore-forming Nav1.6. As such, our findings may prove to be useful for other conditions in which hyperexcitability contributes to the disorder. In, particularly, these results may be relevant to pathologies associated with enhanced resurgent currents such as epilepsy (312, 313).

Figure 32: Proposed working model for Nav1.6 resurgent current modulation. Navβ4 (red cylinder) associates with Nav1.6 (grey tetramer). Part of C-terminal region of Navβ4, also known as the β4 peptide (red sphere), interacts with Nav1.6 to mediate resurgent currents. FHF2A (blue octagon) or FHF2B (green octagon) can bind to the C-terminal region of Nav1.6 and modulate biophysical properties of the channel. FHF2B binding delays fast inactivation (yellow sphere) increasing the probability of the β4 peptide interaction. FHF2A binding to the C-terminus of Nav1.6 also delays fast inactivation but introduces a new competitor which is the long-term inactivation particle (blue sphere) contained within FHF2A's N-terminal domain. If the long-term inactivation particle outcompetes the β4-peptide interaction it results in a decrease of resurgent current generation by Nav1.6.

CURRICULUM VITAE

Cindy M. Barbosa Nuñez

EDUCATION

- Ph.D. Indiana University
 Department of Pharmacology and Toxicology
 Indianapolis, IN
 Advisor, Theodore R. Cummins, Ph.D.
- B.S. University of Puerto Rico
 Department of Chemistry
 San Juan, PR
 Advisor, Jorge L. Colón, Ph.D.

HONORS AND AWARDS

- K.K. Chen Fellowship Award, Indiana University, 2015
- F31 (NS090837-01) Predoctoral Ruth L. Kirschstein National Research Service Award (NRSA), National Institute of Neurological Disorders and Stroke, NIH, 2014.
- Society for Neuroscience (SfN)-Neuroscience Scholars Program Associate, 2014-16
- Society for Advancement of Hispanic/Chicanos and Native Americans in Science Chapter at Indiana University Purdue University Indianapolis, President, 2014-15
- American Pain Society Young Investigator Travel Award, 2014
- Paradise Travel Award, Indiana University, 2013
- Indiana University School of Medicine Graduate Student Travel Award, 2013
- Summer Program in Neuroscience, Ethics and Survival (SPINES) Fellowship, Marine Biological Laboratory, 2013
- National Institute of Neurological Disorders and Stroke Diversity Supplement Award, NIH (NS053422), 2012-2015
- American Association for the Advancement of Science (AAAS)/Science Program for Excellence in Science, 2012-14
- Research Initiative for Scientific Enhancement Internship, University of Puerto Rico, 2009-2010
- Outstanding Poster Presentation Award (Physiology Category), Annual Biomedical Research Conference for Minority Students, 2009
- T-35 Summer Fellowship, Indiana University, 2009
- Academic Excellence in Science and Mathematic Award, University of Puerto Rico, 2009
- Academic Excellence in Science and Mathematic Award, University of Puerto Rico, 2008

- Academic Excellence in Science and Mathematic Award, University of Puerto Rico, 2007
- Puerto Rico-Louis Stokes Alliances for Minority Participation Summer Internship, University of Puerto Rico, 2007

PUBLICATIONS UNDER REVIEW

- **Barbosa C**, Johnson A and Cummins TR. FHF2 isoform differentially regulate Nav1.6 mediated resurgent sodium currents in dorsal root ganglion neurons. Submitted.

PUBLICATIONS IN PREPARATION

- Xiao Y, **Barbosa C**, Cummins TR. Increased resurgent sodium currents in Nav1.8 contribute to nociceptive sensory neurons hyperexcitability in small fiber neuropathy. In preparation

ABSTRACTS

- Xiao Y, **Barbosa Nunez C** and Cummins TR. Increased resurgent sodium currents in Nav1.8 contribute to nociceptive sensory neuron hyperexcitability in small fiber neuropathy. *Soc Neurosci Abstracts*. October 17-21, 2015.
- **Barbosa Nunez C** and Cummins TR. FHF2A negatively regulates resurgent currents in sensory neurons. *Soc Neurosci Abstracts*. October 17-21, 2015.
- Patel RR, **Barbosa Nunez C** and Cummins TR. Epilepsy associated mutant voltage-gated sodium channels alter resurgent current generation that could be preferentially targeted with cannabidiol. *American Epilepsy Society Conference*. December, 2014.
- Patel RR, **Barbosa Nunez C** and Cummins TR. Epilepsy associated mutant voltage-gated sodium channels alter resurgent current generation that could be preferentially targeted by cannabidiol. *Soc Neurosci Abstracts*. November 15-19, 2014.

- **Barbosa Nunez C**, Wang R, Xie W, Tan Z, Strong JA, Vasko MR, Zhang JM and Cummins TR. Nav β 4 in sensory neurons regulates resurgent currents and excitability. Soc Neurosci Abstracts. November 15-19, 2014.
- Xie, W, Tan, Z, **Barbosa Nunez, C.**, Strong, JA, Cummins, TR and Zhang, JM. (2014). Role of Nav β 4 regulatory subunit and resurgent current in development of pathological pain. Soc Neurosci Abstracts. November 15-19, 2014.
